Ground-based aircraft trajectory prediction is a major concern in air traffic control and management. A safe and efficient prediction is a prerequisite to the implementation of automated tools that detect and solve conflicts between trajectories. This paper focuses on the climb phase, because predictions are much less accurate in this phase than in the cruising phase.

Trajectory prediction usually relies on a point-mass model of the forces acting on the aircraft to predict the successive points of the future trajectory. The longitudinal acceleration and climb rate are determined by an equation relating the modeled power of the forces to the kinetic and potential energy rate. Using such a model requires knowledge of the aircraft state (mass, current thrust setting, position, velocity, etc.), atmospheric conditions (wind, temperature) and aircraft intent (thrust law, speed intent). Most of this information is not available to ground-based systems.

In this paper, we improve the trajectory prediction accuracy by learning some of the unknown point-mass model parameters from past observations. These unknown parameters, mass and thrust, are adjusted by fitting the modeled specific power to the observed energy rate. The thrust law is learned from historical data, and the mass is estimated on past trajectory points. The adjusted parameters are not meant to be exact, however they are designed so as to improve the energy rate prediction. The performances of the proposed method are compared with the results of standard model-based methods relying on the Eurocontrol Base of Aircraft DAta (BADA), using two months of radar track records and weather data.

1. Introduction

Ground-based aircraft trajectory prediction is central to most applications in Air Traffic Control and Management (ATC/ATM) and has become more so with the emergence of new operational concepts (SESAR Consortium, 2007; Swenson et al., 2006) envisioning trajectory-based operations. Moreover, trajectory prediction accuracy is essential to the new automated tools and algorithms that have emerged in the recent years. Some of these algorithms require to test a large number of alternative trajectories. As an example, in Prats et al. (2010) an iterative quasi-Newton method is used to find trajectories for departing aircraft, minimizing the noise annoyance. Another example is (Chaloulos et al., 2010) where Monte Carlo simulations are used to estimate the risk of conflict between trajectories, in a stochastic environment. Some of the automated tools

Currently being developed for ATC/ATM can detect and solve conflicts between trajectories, using Genetic Algorithms (Durand et al., 1996), or Differential Evolution or Particle Swarm Optimization (Vanaret et al., 2012). To be efficient, these methods require a fast and accurate trajectory prediction, and the capability to test a large number of “what-if” trajectories.

*These algorithms are at the root of the strategic deconfliction through speed adjustments developed in the European ERASMUS project (Drogoul et al., 2009). A more recent application is the SESAR 4.7.2 (Separation Task in En Route Trajectory-based Environment) project, where lateral and vertical maneuvers are also used.*
Such requirements forbid the sole use of on-board trajectory prediction, which is certainly the most accurate, but is not sufficient for these most promising applications. So, even with the existing or future datalink capabilities that could transmit the on-board prediction to the ground systems, there remains a need for a fast and accurate ground-based prediction.

Unfortunately, ground-based trajectory predictors use point-mass models with unknown or uncertain inputs. Point-mass models relate the inertial acceleration to the forces acting on the center of mass. Such a model is formulated as a set of differential algebraic equations that must be integrated over a time interval in order to predict the successive aircraft positions, knowing the aircraft initial state (mass, current thrust setting, position, velocity, bank angle, etc.), atmospheric conditions (wind, temperature), and aircraft intent (thrust profile, speed profile, route, for example). Most of this information is either not available to ground systems, or known with uncertainty. In this paper, we focus on climb prediction, which is currently fairly inaccurate due to the basic assumptions currently being made on the input values of the point-mass model (e.g.: standard reference mass, reduced power climb at a given calibrated airspeed or Mach number).

Machine Learning is a paradigm of Artificial Intelligence, where a machine (e.g. a computer) extrapolates from a set of examples, so that it can make accurate predictions about future examples. Following this line, our approach is to learn some of the unknown point-mass model parameters from observations, in order to improve the trajectory prediction accuracy. Previous research studies have already followed this path, using probabilistic methods (Lymperopoulos et al., 2006), online learning (Hadjaz et al., 2012), or adaptive adjustments of some modeled parameters (Slater, 2002; Warren and Ebrahimi, 1998; Warren, 2000; Schultz et al., 2012). Considering a climbing aircraft, the past trajectory points are used to adjust either a modeled aircraft mass (assuming a standard thrust profile), or a modeled thrust (assuming a standard reference mass), so as to minimize the error between the model and the observation. In Alligier et al. (2012), we introduce a Machine Learning approach where an optimal thrust law is learned from historical data, and where the individual aircraft masses are estimated from past trajectory points. The preliminary results show a good fit of the modeled power to the observed energy rate. In Alligier et al. (2013), the proposed mass estimation method is compared with the adaptive mechanism of Schultz et al. (2012), showing better performances on simulated data.

In the present publication, we show how the thrust law learned from examples and the estimated mass enhance the altitude prediction when compared with the standard BADA predictor and several of its variants. Contrary to most previous studies that use only simulated data (or small samples of real data, for one of them), we validate the proposed method on a large amount of real data, using two months of recorded climbing trajectories from aircraft departing from the Paris-Orly and Paris-Charles-de-Gaulle airports. In addition, the mass estimation method is extended to the use of a BADA reduced climb power. An empirical assessment of the trajectory prediction quality is also given, considering how the model performs on the past trajectory.

One of these studies (Lymperopoulos et al., 2006) also models the wind as a stochastic variable.
The rest of the paper is organized as follows: Section 2 describes the models and equations that are useful for climb prediction. Section 3 introduces the analytical method used to estimate the aircraft mass, for a given thrust law. Section 4 describes how the optimal thrust law is learned from historical data. We show in Section 5 how the inferred thrust law and estimated mass can be used for prediction purposes. The real data and experimental setup used in our experiments are detailed in Section 6, and results are shown in Section 7. The last section concludes and gives some perspectives of future research.

2. Models and equations

2.1. The second Newton’s law and point-mass model equations

Ground-based trajectory predictors for air traffic management and control usually rely on a simplified point-mass model to predict aircraft trajectories. In such a model, all forces acting on the aircraft body are exerted at the center of mass, making several simplifying approximations. The inertial moments and angular accelerations of the aircraft around its center of gravity are not included in the model. The aircraft is modeled as a point of mass subject to the second Newton’s law that gives us the inertial acceleration \( \ddot{\mathbf{a}} = \mathbf{Thr} + \mathbf{D} + \mathbf{L} + mg \) of the center of mass (the dot above a vector denotes the time derivative of this vector):

\[
m\ddot{V}_i = \mathbf{Thr} + \mathbf{D} + \mathbf{L} + mg \tag{1}
\]

In Eq. (1), mass is considered a stationary variable\(^4\) regarding its impact on the aircraft dynamics. At a larger scale, however, the fuel burn and the consequent loss of mass must be taken into account when integrating the equations to predict the future trajectory. Concerning the forces, it is assumed that the thrust \( \mathbf{Thr} \) exerted by the aircraft engines is aligned to the airspeed \( \mathbf{V}_s \) and in the same direction. The drag \( \mathbf{D} \) exerted by the relative wind on the flying airframe is also aligned to \( \mathbf{V}_s \), by definition, and in the opposite direction. The lift force \( \mathbf{L} \) caused by the motion of the airframe through the air is perpendicular to these vectors and in the plane of symmetry of the aircraft. The flight is assumed to be symmetric and there is no aerodynamic sideforce. The effects of Earth rotation on the aircraft dynamics are neglected (flat Earth approximation).

With the above simplifying approximations, and by expressing the forces in adequate coordinate systems, Eq. (1) can be transformed into the three following scalar equations governing the aircraft dynamics:

\[
\vec{V}_a = \frac{\mathbf{Thr} - \mathbf{D} - g \sin \gamma_a}{m} - \frac{\mathbf{W} \cdot \vec{V}_s}{V_s} \tag{2}
\]

\[
\dot{\gamma}_a = \frac{L \cos \Phi}{mV_a} \cos \gamma_a + \frac{g \cos \gamma_a}{V_a} + \frac{1}{mV_a} \left[ W_N \sin \gamma_a \cos \Psi_a + W_T \sin \gamma_a \sin \Psi_a - W_{dp} \cos \gamma_a \right] \tag{3}
\]

\[
\Psi_a = \frac{L}{mV_a} \left( \sin \theta_a \sin ^2 \gamma_a \cos \Phi + \cos \theta_a \sin \Phi \right) - \left( \frac{\mathbf{Thr} - \mathbf{D}}{mV_s} \right) \sin \theta_a \cos \gamma_a \tag{4}
\]

2.2. The total energy model equations, with the effect of wind

Introducing the pressure altitude \( H_p \) and a temperature correction that accounts for the use of the pressure altitude instead of the geodetic altitude, Eq. (2) can be written as follows:

\[
\text{Power} = \frac{\text{specific power}}{m} = V_a \frac{dV_a}{dt} + \frac{B_0}{T} \left( \frac{T - \Delta T}{T} \right) \frac{dH_p}{dt} + \frac{dW}{dt} \cdot \vec{V}_s \tag{5}
\]

In this equation, the vertical component of the wind is assumed to be zero because of the lack of sufficient information. In our data, the wind is known through a weather model updated every 3 h. The vertical wind, as a local phenomenon due for example to convective weather, is out of the scope of such a weather model, which aims at providing wind data for Air Traffic Management purposes on a large scale. Such assumptions are most common in the literature dealing with similar subjects (see Slattery and Zhao (1997) for example). Note however that the effect of the wind gradient – i.e. the changes in direction and magnitude of the horizontal wind while moving along the vertical axis – is taken into account.

Eq. (5) governs the energy rate of the aircraft, and relates both the longitudinal acceleration \( \ddot{V}_a \) and the rate of climb \( \frac{dH}{dt} \) to the power of the forces exerted at the center of mass (see Nuic (2011) for more details). The power is defined as follows:

\[
\text{Power} = (\mathbf{Thr} - \mathbf{D})V_a \tag{6}
\]

\(^4\) We assume in fact that \( \frac{d}{dt} (m\vec{V}_i) = m\ddot{V}_i \), and neglect the impact of \( m \) on the acceleration.
Considering the term representing the energy rate in the right-hand side of Eq. (5), we see that the available power that
goes to the aircraft motion is shared between longitudinal acceleration \( \frac{dV}{dt} \) and climb (or descent) rate \( \frac{dH}{dt} \). The energy share factor \( \text{ESF} \) is defined as follows:

\[
\text{ESF} = \frac{g_0 \left( \frac{T}{T - \Delta T} \right) \frac{dH}{dt} \frac{\text{Power}}{m} \left( \frac{dV}{dt} \right) V_a}{g_0 \left( \frac{T}{T - \Delta T} \right) \frac{dH}{dt} + g_0 \left( \frac{T}{T - \Delta T} \right) \frac{\text{Power}}{m} \left( \frac{dV}{dt} \right) V_a} = \left[ 1 + \left( \frac{T - \Delta T}{T} \right) \left( \frac{V_a}{g_0} \right) \left( \frac{dV}{dt} \right) \right]^{-1}
\]

This energy share between longitudinal acceleration and rate of climb is directly related to how the aircraft is operated by
the pilot (or the autopilot). Eq. (7) does not come from a physical law as Eq. (5), but is just a definition of a quantity reflecting
the pilot’s choice, that is usually unknown to ground-based systems.

Eq. (5) is sufficient when estimating the mass or learning the optimal thrust law from historical data, making no assumptions
of the input variables, which is a critical issue considering all the unknowns and uncertainties on these variables.

## 2.3. Computing the aircraft trajectory, assuming complete and accurate information

Knowing the initial state \((H_p, V_a, m)\), the fuel flow given by the BADA model, and the two laws chosen for the thrust setting \( c \) and energy share factor \( \text{ESF} \), we can compute the variations of the state variables \( H_p, V_a \) and \( m \) over time, using Eqs. (5) and (7).

Considering Eq. (5), the definition of the ESF given in Eq. (7) is completely equivalent to the following formulation:

\[
g_0 \left( \frac{T}{T - \Delta T} \right) \frac{dH}{dt} = \left( \frac{\text{Power}}{m} \frac{dV}{dt} V_a \right) \text{ESF}
\]

Denoting \( \tau \) the ratio \( \frac{T}{T - \Delta T} \), these equations can be reformulated into the differential algebraic Eq. (9):

\[
\frac{1}{2} \frac{1}{g_0 \tau} \left( \frac{dV^2}{dt} \right) \left( \frac{\text{Power}}{m} - \frac{dW}{dt} V_a \right) = \frac{1}{g_0 \tau} \left( \frac{dV}{dt} \right) \left( \frac{1}{\text{ESF}} \right)
\]

When integrating Eq. (9) over time, we can compute the future altitude and speed of the aircraft as illustrated with the Eq.
(10):

\[
\left( \frac{V^2}{H_p} \right) - \left( \frac{V_0^2}{H_p} \right) = \int_0^t \left( \frac{\text{Power}}{m} - \frac{dW}{dt} V_a \right) \left( \frac{1}{2} \frac{1}{g_0 \tau} \right) \left( \frac{1}{\text{ESF}} \right) dt
\]

Eq. (10) shows the key elements of aircraft trajectory prediction: mass, power, energy share factor, and weather (wind and air temperature). These are also the potential sources of uncertainty with which ground-based trajectory predictors have to deal.

## 2.4. Model of the forces and power

Computing a trajectory requires a computational model of the aerodynamic drag \( D \) of the airframe flying through the air,
and of the engines’ thrust \( \text{Thr} \). In our experiments, we used version 3.9 of the Eurocontrol BADA model (see Nuic (2011)) to compute the drag \( D \) and the maximum climb thrust \( \text{Thr}_{\text{max-climb}} \).

More accurate BADA models exist (BADA 4 family, Nuic et al., 2005), and are available under license, for a smaller number
of aircraft types. They actually model the aircraft dynamics more accurately than BADA 3.9 (Poles et al., 2010), fitting the
manufacturer data better and making fewer simplifying assumptions. These enhancements are useful, especially for realistic
simulations.

However, we are not actually looking for a more accurate point-mass model, here. Our aim is rather to improve the estimation
of the input variables, which is a critical issue considering all the unknowns and uncertainties on these variables when
using the point-mass model as a ground-based predictor. BADA 3.9 is sufficient for our purpose, in this context.

Considering the equations found in Nuic (2011), \( \text{Thr}_{\text{max-climb}} \) is simply a function of \( H_p, \Delta T \), and \( V_a \) and the drag \( D \) can be expressed as a polynomial of the mass \( m \), which coefficients are functions of the other state variables:

\[
\text{Thr}_{\text{max-climb}} = f_1(H_p, V_a, \Delta T) \quad \text{(11a)}
\]

\[
D = f_2(H_p, V_a, \Delta T) + m^2 f_3(H_p, V_a, \Delta T, \Phi) \quad \text{(11b)}
\]

As aircraft do not always fly at the maximum climb thrust in reality, we introduce a thrust reduction coefficient \( c \), and
model the thrust as follows:

\[
\text{Thr} = c \text{Thr}_{\text{max-climb}} \quad \text{(12)}
\]
The power \((\text{Thr} - D)/V_a\) can then be expressed as a function of the thrust setting coefficient \(c\), the mass \(m\), and the other state variables:

\[
\text{Power} = (c\text{Thr}_{\text{max/limb}} - D)/V_a = (cf_1(H_p, V_a, \Delta T) - f_2(H_p, V_a, \Delta T) - m^2f_3(H_p, V_a, \Delta T, \Phi)/V_a
\] (13)

At this point, it is important to notice that the power, given either by Eq. (13) or by the BADA equation for the reduced power climb (Nuic, 2011), is a polynomial with respect to the mass \(m\). This allows us to devise simple analytical methods to estimate the mass from the observations, as shown in the next section.

2.5. Modeling the thrust setting law \(c = f(\cdot, \theta)\)

The law governing the thrust setting \(c\) can be modeled as a function \(f(\cdot, \theta)\) parametrized by \(\theta = (\theta_1, \ldots, \theta_q)\), a vector of \(q\) parameters. This law is assumed to be the same for all aircraft belonging to a given category. In the current paper, one such category contains all aircraft of a same type departing from a same airport. Further refinements may consider aircraft belonging to a same airline, or different categories for typical climb profiles extracted from the data.

Considering a set of trajectories with the same thrust setting law \(f(\cdot, \theta)\), the thrust coefficient at point \(i\) of a trajectory \(k\) is simply \(c_{iki} = f(x_{iki}, \theta)\), with \(x_{iki}\) a vector of state variables \((\text{altitude } H_p, \text{velocity } V_a, \text{bank angle }\), temperature differential \(\Delta T)\), for example) measured or computed at the \(i\)th point.

In order to learn the thrust law \(f(\cdot)\) (see Section 4) that gives the best prediction performances when used together with the estimated masses (see Section 3), we need to choose a model for this law. This arbitrary choice may depend on the data made available to the ground-based predictor. As a proof of concept, we have chosen two models: one for the general case, and another one for the case of aircraft following a constant CAS/Mach climb, with the target CAS and Mach number known to the ground systems.

For the first model, used for Case Study 1 of Section 7.3, we have chosen a polynomial function of the pressure altitude \(H_p\):

\[
f(x|\theta) = \sum_{i=0}^{4} a_i(H_p)^i
\] (14)

For the second model, when considering CAS/Mach climbs with known target calibrated airspeed and Mach number, we have an opportunity to use this knowledge of the aircraft intent in the thrust law itself. This is done by introducing the crossover altitude \(H_p^{\text{cross}}\) in the polynomial function modeling the thrust setting. The following law is used in Case Study 2 of Section 7.3:

\[
f(x|\theta) = \sum_{i=0}^{4} a_i \left(H_p - H_p^{\text{cross}}\right)^i (\text{CAS}_k, M_k)
\] (15)

3. Mass estimation, knowing the thrust setting

Using Eq. (5), the mass \(m\) can be estimated in a very simple way for a given thrust setting \(c\). The specific power is a polynomial with respect to the mass \(m\), and we can measure the energy rate \(V_a \cdot \frac{dV_a}{dt} + g \cdot \frac{dh}{dt} + \Phi \cdot \frac{d\Phi}{dt}\) and wind effect \(\frac{dW}{dt}\). \(V_a\) from recorded weather and radar data. Note that the mass can be estimated without making any assumption on the ESF law.

3.1. Equivalent mass at a given point

Introducing the total energy \(\text{Energy} = \frac{1}{2}mV_a^2 + mgh\) and considering Eq. (5), let us introduce \(P\) and \(Q\), defined as follows:

\[
P = \text{Power} - m \left[\frac{d}{dt} \left(\frac{\text{Energy}}{m}\right) + \frac{dW}{dt} \cdot \frac{V_a}{q}\right]
\] (16a)

\[
Q = V_a \frac{dV_a}{dt} + g_0 \left(\frac{T}{T - \Delta T}\right) \frac{dH}{dt} + \frac{dW}{dt} \cdot \frac{V_a}{q}
\] (16b)

The quantity \(Q\) can be computed at any point of the past trajectory, or at any point of a recorded trajectory, using the available radar and weather information. Considering the power model given by Eq. (13) in Section 2.2, we see that \(P\) is a simple polynomial function of the second degree with respect to the aircraft mass \(m\), when the thrust setting \(c\) is fixed. So the total energy model Eq. (5) becomes:

\[
P(m) = 0
\] (17)

with

\[
P(m) = -m^2f_3(H_p, V_a, \Delta T, \Phi) - mQ + cf_1(H_p, V_a, \Delta T) - f_2(H_p, V_a, \Delta T)
\] (18)
These equations are valid at any given point $i$ of the past trajectory, knowing $V_{ai}$, $H_{ai}$, $\Delta T$ and the thrust setting $c$. The equivalent mass $m_i$ at point $i$ is obtained by solving Eq. (17), giving us two possible solutions. In our experiments, only one solution was positive.

3.2. Least squares estimation of the mass, using several points

With the one-point method presented in the previous section, we observed on a few recorded trajectories that the estimated mass changes from one point to the next. In order to avoid the variations that cannot be explained solely by the fuel consumption or by a change in the thrust setting, we now introduce a least-squares approximation of the mass, using several points instead of only one.

Let us consider $n$ points in a given climb segment, with different values of the thrust settings $C = \{c_1, \ldots, c_n\}$. The mass is assumed to be constant over the considered segment. This approximation is reasonable: When simulating the climb of an Airbus A320 from FL130 to FL300 with the BADA model, in ISA + 20 atmospheric condition, we find a fuel consumption of 1,075 kg, that is to say 1.68% of the initial mass, chosen as the BADA reference mass.

Note that we do not try to adjust the thrust coefficients $C = \{c_1, \ldots, c_n\}$ here. Assuming a constant mass $m$ for the $n$ considered points, we adjust $m$ so as to minimize the following mean square error, given the thrust settings $(c_1, \ldots, c_n)$:

$$
E_{\text{sq}}(C, m) = \frac{1}{n} \sum_{i=1}^{n} \left( \frac{\text{Power}_i(m)}{m} - Q_i \right)^2
$$

Denoting $P_i(m)$ the value at point $i$ of the polynomial expression $P$ given by Eq. (17), the error becomes:

$$
E_{\text{sq}}(C, m) = \frac{1}{n} \sum_{i=1}^{n} \left( \frac{P_i(m)}{m} \right)^2
$$

The minimum of $E_{\text{sq}}$ must satisfy $\frac{\partial E_{\text{sq}}}{\partial m} = 0$, which gives us the following equation, with $P'_i(m)$ the derivative of $P_i(m)$ with respect to $m$:

$$
\sum_{i=1}^{n} P_i(m) \left[ mP'_i(m) - P_i(m) \right] = 0
$$

This fourth-degree polynomial Eq. (21) is solved using Ferrari’s method. Among the four potential solutions, we select the solution in $[0, +\infty[$ minimizing $E_{\text{sq}}(C, m)$.

3.3. Equivalent mass in the case of a BADA reduced climb power

We have seen how to estimate the mass at a given point (Section 3.1) or using several trajectory points (Section 3.2) when the power is modeled as described in Eq. (13). These methods can still be applied when assuming the BADA maximum climb, by setting $c = 1$ in Eq. (18).

When considering the BADA reduced climb power, however, the expression of $P_i(m)$ is no longer the same. In this case, the power is given by $\text{Power}_{\text{BADA}}$, described in the following Eq. (22), where $C_{\text{pow,red}}$ is the BADA power reduction coefficient depending on the mass and the maximum altitude $H_{\text{max}}$ (see Nuic, 2011):

$$
\text{Power}_{\text{BADA}} = C_{\text{pow,red}}(\text{Thr}_{\text{max,climb}} - D)V_a
$$

Using the BADA power reduction profile, we have the following equation for $P_i(m)$, which is still a polynomial function of the mass, as in Section 3.1, but of the 3rd degree below $0.8H_{\text{max}}$, and of the 2nd degree above:

$$
P_i(m) = \text{Power}_{\text{BADA}} - mQ = C_{\text{pow,red}}(m)[-m^2f_3(a_H, V_a, \Delta T, \Phi) - f_2(a_H, V_a, \Delta T) + f_1(a_H, V_a, \Delta T)] - mQ
$$

The equivalent mass can still be found by solving the polynomial Eq. (21), except that $P_i(m)$ is of the 2nd or 3rd degree, depending on the altitude of the considered points. In our experiments, when estimating the equivalent mass of an Airbus A320 using points below 18,000 ft and assuming a BADA reduced climb power, the inequality $H_p \leq 0.8H_{\text{max}}(\Delta T, m)$ can reasonably be assumed to be true.⁵ In that case, $P_i(m)$ in Eq. (21) is a third-degree polynomial.

In any case, we have a simple method to estimate an equivalent mass from a few points of the trajectory, given the thrust law for these points.

4. Learning the thrust law from historical data

We have seen in Section 3 how to estimate the mass. Now, let us see how to learn the thrust setting law, using a set of recorded trajectories and a regression method coupled to our mass estimation method.

---

⁵ Numerical application sets 0.8 $H_{\text{max}}$ at 19,144 ft for $\Delta T$ at 40 K and $m$ at 77,000 kg.
4.1. Discussion

We cannot infer both the mass and thrust setting law from Eq. (5) using only the past trajectory of one given aircraft: Denoting $C_{\text{past}} = (c_1, \ldots, c_n)$ the thrust coefficient for the past $n$ points, there is an infinity of couples $(C_{\text{past}}, m)$ fitting the observed energy rate perfectly. Intuitively, high thrust with a large mass $m$ barely produces the same amount of specific power as low thrust with a small mass $m$.

In a prediction context, we need to compute the specific power for the next $p$ points, which requires some assumptions on the future thrust settings $(c_{n+1}, \ldots, c_{n+p})$. As this data is not available to ground systems, it is usual to make an "educated guess", assuming maximum climb thrust or reduced power climb for example, and to estimate an equivalent mass that is consistent with this choice, using the first trajectory points. As an alternative to this method, we propose to learn an optimal thrust law from historical data, choosing the law that minimizes the prediction error on a set of recorded trajectories.

4.2. Learning a thrust law from data

We are looking for a thrust setting law $c = f(\theta)$ that is common to all aircraft of a same category. Given this law, the thrust setting coefficients $c_i = (c_{i1}, \ldots, c_{in})$ for the $n_k$ points of a sampled trajectory $k$ are given by the following expression (24), with $x_{kj}$ a vector of state variables measured at the $i$th point:

$$C_i(\theta) = f(x_{k1}(\theta), \ldots, f(x_{kn}(\theta)))$$

Considering a set of $K$ trajectories taken from historical data, we are looking for a value of $\theta$ that minimizes the overall quadratic error $E_{\text{Total}}$, as defined by the following Eqs. (25):

$$m_k^*(\theta) = \arg\min_{m_k \in C_0 \cup C_1} E_{k}(C_k(\theta), m_k)$$

$$E_{\text{Total}}(\theta) = \sum_{k=1}^{K} E_{k}(C_k(\theta), m_k^*(\theta))$$

The optimal mass $m^*$ for any given $\theta$ is obtained by solving a polynomial equation using Ferrari’s method, as presented in Section 3.2.

In Eqs. (25), $E_k$ is the quadratic error for trajectory $k$, as given by Eqs. (19) and (20) (see Section 3.2). To be more explicit we can write $E_k$ as follows:

$$E_k(C_k, m_k) = \frac{1}{n_k} \sum_{i=1}^{n_k} \left( \frac{P_{\text{total}}(c_{ik}, m_k)}{m_k} \right)^2$$

$$P_{\text{total}}(c_{ik}, m_k) = \text{Power}_{\text{total}}(m_k, c_k) - m_k Q_{\text{total}}$$

$$\text{Power}_{\text{total}}(m_k) = (c_k \text{Thr}_{\text{maxclimb}k} - D_{\text{total}}) V_{ak,i}$$

with $Q_{\text{total}}$ the value at point $i$ of trajectory $k$ of the quantity $Q$, the sum of the specific energy rate and wind effect, defined by Eq. (16b). The maximum climb thrust $\text{Thr}_{\text{maxclimb}}$ is given by the BADA equations as a function of the vector of state variables $x_{kj}$. The drag $D$ is also provided by the BADA model, as a function of $x_{kj}$ and $m_k$.

An iterative quasi-Newton method (BFGS) is used to find a vector $\theta^*$ minimizing $E_{\text{Total}}(\theta)$. The BFGS method (Broden-Fletcher-Goldfarb-Shanno, from the names of its authors) approximates the Hessian matrix at each iteration, using the gradient of the error function $\nabla E_{\text{Total}}$. The reader may refer to Nocedal and Wright (2006) for further details on the method.

The gradient of the error can easily be computed in our problem. The partial derivative of the error on trajectory $k$ with respect to one parameter $\theta_i$ of vector $\theta$ is the following, considering that $\frac{\partial E_k}{\partial \theta_i} (c_k, m_k) = 0$, by definition of $m_k^*$:

$$\frac{\partial E_k}{\partial \theta_i} (c_k, m_k^*) = \frac{\partial}{\partial c_i} (C_k, m_k^*) \frac{\partial m_k^*}{\partial \theta_i} + \sum_{i=1}^{n_k} \frac{\partial}{\partial c_{ik}} (C_k, m_k^*) \frac{\partial c_{ik}}{\partial \theta_i} = \sum_{i=1}^{n_k} \frac{\partial}{\partial c_{ik}} (C_k, m_k^*) \left( \frac{\partial f_i(x_{ki})}{\partial \theta_i} \right)$$

Using the Eq. (26a) defining $E_k$ and the above Eq. (27), we find the following expression for the partial derivative:

$$\frac{\partial E_k}{\partial \theta_i} (c_k, m_k^*) = \frac{2}{n_k} \sum_{i=1}^{n_k} \left( \frac{P_{\text{total}}(m_k^*, c_k) V_{ak,i} \text{Thr}_{\text{total}}(x_{ki})}{m_k^*} - \frac{\partial f_i(x_{ki})}{\partial \theta_i} \right)$$

Finally, the components of the overall gradient vector $\nabla E_{\text{Total}}$ are the following:

$$\frac{\partial E_{\text{Total}}}{\partial \theta_i} (\theta) = \sum_{k=1}^{K} \frac{\partial E_k}{\partial \theta_i} (\theta)$$

Eqs. (25) and (29) are applied on a set of recorded trajectories to compute the total error and its gradient. Using these two functions of $\theta$, the BFGS method finds the vector of adjusted parameters $\theta^*$ minimizing $E_{\text{Total}}(\theta)$. At each step of the BFGS search, the mass estimation method presented in Section 3.2 is used to find the optimal masses $(m_1^*(\theta^*), \ldots, m_n^*(\theta^*))$ corresponding to the candidate vector $\theta$ being evaluated. At the end of the search, we have the optimal $\theta^*$ and the optimal masses $(m_1^*(\theta^*), \ldots, m_n^*(\theta^*))$ for the chosen trajectory set.
The learning phase described above provides us with a thrust setting law \( f(x, \theta^0) \) which can then be used for prediction purposes on fresh trajectories. If the sample of historical data used for learning is sufficiently representative of the actual traffic (as we hope it is), the proposed method will generalize well when applied to prediction. The learned thrust law may not actually reflect the actual thrust settings of each individual aircraft, but it is designed so as to improve the predicting performance when coupled with the equivalent mass estimation method described in Section 3.2.

The choice of the parametric function \( f \) for the thrust law is not discussed here. We have chosen a simple fourth-degree polynomial function of the pressure altitude \( H_p \), as a proof of concept. Experimenting different choices for \( f \) could be the subject of future works.

5. Using the inferred mass and thrust law for prediction purposes

Predicting the future trajectory of a climbing aircraft with the mass estimation method presented in Section 3.2 and the thrust law learned from historical data is quite straightforward. Let us assume that we have observed \( n \) points of the past trajectory, with one point every \( \Delta t \) seconds, and that we want to predict the next \( p \) points of the future trajectory.

The thrust setting coefficients \( c_1, \ldots, c_n \) for the past \( n \) points are computed using the thrust law \( f(x, \theta^0) \) learned from historical data (see Section 4.2). Knowing the values of the state variables \( x^{(hi)} \) (air temperature, aircraft altitude, velocity, etc.) for the past trajectory, the coefficients are simply \( c_i = f(x^{(hi)}(\theta^0)) \), for all \( i \in \{1, \ldots, n\} \). The equivalent mass \( m \) is then estimated from the past trajectory, using these thrust setting coefficients and the method presented in Section 3.2.

Computing the thrust settings \( (c_{n+1}, \ldots, c_{n+p}) \) for the next \( p \) points is more difficult, as we need the predicted values of the state variables \( x^{(pred)} \). This requires to integrate Eq. (9) over the time interval \([t_n, t_{n+p}]\). Eq. (10) shows the mathematical form of this integral of the ESF and specific power. In general, this equation cannot be solved analytically, and numerical methods must be used. Using for example the Euler method with a time step \( \delta t \) (or Runge–Kutta methods), we can compute the successive values of the predicted state variables and thrust setting coefficients.

6. Data and experimental setup

6.1. Data pre-processing

Recorded radar tracks from Paris Air Traffic Control Center are used in this study. This raw data is made of one position report every 1–3 s, over two months (July 2006 and January 2007). In addition, the wind and temperature data from Météo France are available at various isobar altitudes over the same two months.

The pressure altitude is reported by increments of 100 ft (ICAO, 2007) by the Mode-C radars. A local quadratic model is used to smooth our raw data. After smoothing, the basic trajectory data is made of the following fields: aircraft position \((X, Y)\) in a projection plan, or latitude and longitude in WGS84, ground velocity vector \( V_g = (V_x, V_y) \), smoothed altitude \( H_p \) in feet above isobar 1013.25 hPa, rate of climb or descent \( \frac{dt}{dx} \). The wind \( W = (W_x, W_y) \) and temperature \( T \) at every trajectory point are interpolated from the weather datagrid. The temperature differential \( \Delta T \), which is the difference between the actual temperature and the temperature given by the ISA model, is computed at each point. This \( \Delta T \) is one of the key parameters in the BADA model equations.

Using the position, velocity and wind data, we compute the true airspeed \( V_a \), the distance flown in the air, the drift angle, the along-track and cross-track winds \( (W_{along}, W_{cross}) \). The successive velocity vectors allow us to compute the trajectory curvature at each point. The aircraft bank angle is then derived from true airspeed and the curvature of the air trajectory. The climb, cruise, and descent segments are then identified, using triggers on the rate of climb or descent to detect the transitions between two segments.

6.2. Filtering and sampling climb segments

To demonstrate the performance of the proposed method, we focus on a single aircraft type (Airbus A320). Our dataset comprises all flights of this type departing from Paris-Orly (LFPO) or Paris-Charles de Gaulle Airport (LFPG). Of course, this approach can be replicated to other aircraft types and airports, and to more specific categories of climbs (e.g. per airline, per departure procedure, etc.) provided sufficient data can be collected.

The trajectories are filtered so as to keep only the climb segments. An additional 80 s is clipped from the beginning and end of each segment, so as to remove climb/cruise or cruise/climb transitions.

The trajectories are then sampled every 15 s so that the time \( t_0 \) of the “current” position corresponds to the crossing of altitude 18,000 ft. The 10 points before \( t_0 \) represent the “past trajectory”, below FL180. The 40 points after \( t_0 \) represent the “future” trajectory (10 min ahead \( t_0 \)). The first 11 points (current point and past trajectory) are used to estimate the equivalent mass. The remaining points (future trajectory) are used to compute the error between the predicted and actual energy rate.
6.3. Two case studies, and cross-validation

As we have seen in Section 2.3, predicting the future trajectory does require some knowledge of the law governing the Energy Share Factor (ESF). Learning the ESF law is not the subject of the work presented here, so in the following, we will either assume that the ESF is perfectly known, or make basic assumptions on the ESF law.

In our experiments, the prediction error of the proposed method is evaluated on two datasets, with two ways to obtain the ESF law. In the first case study, we use all the trajectories of our dataset (5167 trajectories), and we look at the error on the energy rate prediction, assuming that the ESF law is perfectly known. In the second case study, we assume a CAS/Mach climb to compute the ESF, and evaluate the overall performance of the trajectory prediction. In this case, as we have only Mode-C, and not Mode-S radar data that would contain the Calibrated Airspeed (CAS) and Mach number, we simply select the trajectories exhibiting a consistent CAS/Mach profile from our initial dataset.

In both case studies, a 10-fold cross-validation is performed. The set of trajectories is split in ten folds of equal size. Nine folds are grouped together and used as the training set in order to learn the thrust law \( f_x(\theta^j) \). The remaining fold is used as a validation set, to evaluate the prediction performance. The operation is repeated ten times, choosing a different fold as the validation set, in order to cover all possible combinations of couples (training set, validation set).

6.4. Different settings compared

Our prediction method uses one estimated mass \( m_{\text{estimated}} \) per individual aircraft (see Section 3.2) and a common thrust law \( f_x(\theta^j) \) learned on the training set (see Section 4.2). In order to evaluate the performance of the proposed method, it is compared with other model-based prediction methods relying on the BADA model. The BADA methods use a single reference mass for all aircraft of the same type, and either the BADA maximum climb thrust (BADA\(_{\text{maxclimb}}\)) or the BADA power reduction profile (BADA\(_{\text{reduced}}\)), as given by Eq. (22).

The effects of mass estimation and thrust/power law can be evaluated independently by considering all possible combinations of mass and thrust/power law. The possible choices for the law governing the thrust (or the power for BADA\(_{\text{reduced}}\)) during climb are summarized in Table 1. Concerning the mass, we could just compare the performances given by the estimated mass \( m_{\text{estimated}} \) with the performances obtained when using the reference BADA mass \( m_{\text{BADA}} \), which is the usual way to proceed. To be more fair, we have also compared with another mass \( m_{\text{opt}} \), also common to all aircraft but chosen so as to minimize the altitude prediction error on the training set. The mass \( m_{\text{opt}} \) minimizes the root mean square error on the pressure altitude \( H_{p(51)} \) at the last trajectory point, considering all trajectories in the training set. The possible choices for the mass setting are summarized in Table 2.

In our experiments, we compare our method combining \( m_{\text{estimated}} \) and the learned thrust law \( f_x(\theta^j) \) with the six different methods obtained by combining a mass \( m_{\text{BADA}}, m_{\text{opt}}, \) or \( m_{\text{estimated}} \) and a standard thrust/power law (either BADA\(_{\text{maxclimb}}\) or BADA\(_{\text{reduced}}\)). The performances of the seven methods are assessed on the two case studies described in Section 6.3, applying a 10-fold cross-validation. Section 7.3 shows the results (mean value and standard deviation) over the ten runs. Before comparing the seven methods, let us see a few results on the distribution of the estimated masses, and on the learned thrust law.

7. Results

7.1. Estimated mass

Fig. 4 plots the distributions of the estimated masses for the two case studies, and for the three possible laws governing the thrust (or the power in the case of \( BADA_{\text{reduced}} \)) during the climb. We have plotted 10 curves per thrust law, corresponding to the 10 training sets of the cross-validation.

We can see on this figure that the curves of a same thrust law are quite similar. The range of the estimated masses seems quite large for all distributions. The mean values differ from one law to another, which was to be expected as different laws lead to different thrust settings (or reduced power) coefficients and different masses: the higher the thrust setting, the higher the estimated mass.

We cannot compare the estimated masses with the actual aircraft masses, as the latter are not available to us. Therefore, we cannot say which combination of mass estimation method and thrust law provides the most realistic mass distribution. This is not an issue for our problem, however, as we estimate an equivalent mass meant to provide an accurate computation of the specific power, when associated with the adequate thrust law.

![Distributions of \( m_{\text{estimated}} \) for the three thrust profiles \( (BADA_{\text{max climb}}, BADA_{\text{reduced}}, f(\frac{\theta}{\gamma})) \) and for the 10 training sets of the cross-validation.]

![The learned thrust law \( f(\frac{\theta}{\gamma}) \), for the 10 training sets of the cross-validation.]

7.2. Thrust law

Fig. 5 displays the thrust laws learned on the 10 training sets while performing the cross-validation. The thrust profile is very similar for all the training sets. For the case study with all the trajectories (left picture), the thrust setting globally increases with the pressure altitude \( P_0 \) from 0.96 to 1.04. For the CAS/Mach trajectories (right picture), the thrust setting oscillates between 0.90 and 0.95, with a noticeable peak at the CAS/Mach crossover altitude.

7.3. Overall prediction performance

For a given trajectory, the prediction performance is evaluated by measuring the error between the predicted and observed values at equal times, for the \( p \) points of the future trajectory. More explicitly, the prediction error over the \( p \) future points of a given trajectory \( k \) is assessed by measuring \( e^{(\text{pred})}_k = \sqrt{\sum_{i=1}^{p} e_i^2} \), with \( e_i \) given by Eq. (26), using the predicted state variables to compute the specific power. This quantity can be written as follows:

\[
e^{(\text{pred})}_k = \sqrt{\frac{1}{p} \sum_{i=1}^{p} \left( \frac{\text{Power}(m_i^{(\text{pred})}, c_i^{(\text{pred})})}{m_i^{\text{computed}}} - \frac{\mathcal{Q}(x^{(\text{obs})}_i)}{x^{(\text{obs})}_i} \right)^2}
\]

with \( m_i \) the mass of aircraft \( k \) estimated on the \( n \) past and current points (\( n = 11 \) in our experiments), \( c_i^{(\text{pred})} \) is the thrust setting coefficient at the \( i \)th predicted point, and \( \mathcal{Q}(x^{(\text{obs})}_i) \) the observed energy rate and wind effect at the \( i \)th actual point:

\[
e_i = f(x^{(\text{pred})}_i; |\theta^*|)
\]

\[
\mathcal{Q}(x^{(\text{obs})}_i) = \left[ V_a \frac{dV_a}{dt} + f_0 \left( \frac{T}{T - \Delta T} \right) \frac{dH_p}{dt} + \frac{dW}{dt} - V_a \right]^{(i)}
\]

In the above Eq. (31a), \( f_i; |\theta^*| \) is the thrust law learned on the training set, and \( x^{(\text{pred})}_i \) is the vector of state variables (position, velocity, acceleration, etc.) predicted for the \( i \)th point of predicted trajectory \( k \).

For a set of trajectories, the overall error on the specific power prediction is assessed by computing the root mean square error (RMSE) of \( e_k^{(\text{pred})} \). This RMSE is computed for the seven chosen combinations of mass and thrust law (see Section 6.4), for each fold of the cross-validation, the error is measured over the validation set only, using the thrust law learned on the training set.

The mean values and standard deviations (within brackets) of RMSE \( (e_k^{(\text{pred})}) \) are presented in Table 3a and b, together with the \( p \)-values of a Wilcoxon signed-rank paired test comparing our method (last row) to each of the BADA methods. The same table also gives the mean values and standard deviations of the RMSE of \( \Delta H_p \) and \( \Delta V_a \), the altitude and velocity errors, respectively, at the last point of the predicted trajectory (10 min ahead).

We see on Table 3a and b that the methods using the estimated mass \( m_{\text{estimated}} \) have lower root mean square errors when compared with the ones using constant masses \( (m_{\text{BADA}} \text{ or } m_{\text{opt}}) \). So, whatever the chosen thrust/power profile, estimating an

</table>
individual mass for each aircraft is better than using a common mass, even when this single mass is optimized for the given prediction purpose.

Let us remind that the aim of case study 1 (all trajectories and observed ESF) is to compare the prediction performance on the energy rate only, assuming that the Energy Share Factor is perfectly known. So, in Table 3a, we are mostly interested in comparing the errors on $e^{\text{pred}}(k)$. The errors on $D_{H_p}$ and $D_{V_a}$ are given as indications. They are not representative of what could actually be obtained in an operational context, when using an ESF law that can differ from the observed ESF.

The case study 2 (CAS/Mach trajectories and computed ESF), on the contrary, is more representative of what could be obtained in a real context, assuming the target CAS and Mach number to be known (i.e. transmitted by the aircraft via datalink). We use the computed values of the Energy Share Factor that correspond to the target CAS and Mach number.

Our method combining the estimated mass $m_{\text{estimated}}$ with the adjusted thrust law $f(\theta^*)$ performs best among the seven tested methods. The statistical significance of our results is assessed by performing a Wilcoxon signed-rank test. This choice is relevant because all methods are evaluated on a same dataset (split in ten folds), so we have paired samples: we compare two predictions made with two different methods, for a same flight. Using a directional test, the null hypothesis ($H_0$) is that the median of the difference between the two predictions (with our method and the other) is positive, meaning that our method performs equally or worse than the other. The alternative hypothesis ($H_1$) is that the median of the difference is strictly negative, meaning a better performance of our method. The fourth column of Table 3a and b shows the $p$-values for this test. Comparing with the standard threshold of 0.05 for a 95% confidence interval, we can reject $H_0$ and accept $H_1$ as true in all cases.

Let us now look at the altitude prediction, focusing on case study 2 (Table 3b). Looking at the altitude error $D_{H_p}$ in Table 3b, we see that our method (last row of the table) reduces the root mean square error by nearly 40% when compared with the standard BADA maximum climb with the reference mass $m_{\text{BADA}}$ (first row). When comparing with the BADA reduced climb power (third row), the altitude error is reduced by nearly 50%.

7.4. Altitude prediction errors at various future times

Fig. 6 shows the boxplots of the altitude errors at various future times, from the first predicted point 15 s ahead to the last one 10 min ahead, using the standard BADA maximum climb (left figure) or our method (right figure). For each look-ahead time in Fig. 6, the central box represents the 0.25/0.75 interquartile distance, and the whiskers are defined so that the lower one leaves 5% of the data below it, and the upper one leaves 5% above.

We can see that the boxes and whiskers are much narrower and better centered around zero with our method than with the standard BADA method. When using the inferred mass and learned thrust law, the altitude prediction is statistically better at all predicted times.

The kurtosis excess for the results of our method is 6.21, indicating that this distribution is more fat-tailed than the normal one. The distribution obtained with the BADA method, with a kurtosis excess of 0.10, is much closer to the normal distribution.

---

6 We have used the `wilcox.test` provided by the R environment, with the `paired` option.
7 The $p$-value is the probability to be wrong when accepting $H_0$ and rejecting $H_1$.
8 Computed using kurtosis (.,type = 1) of the R package ‘e1071’.
Nevertheless, our method remains significantly more accurate than BADA, as long as one does not require a confidence interval very close to 100%: As can be seen on Fig. 7, the empirical cumulative distribution function of our method is above the BADA one. Thus, when looking for a centered interval containing \( x \% \) of the data, our method will always give a smaller interval than the BADA method.

As can be seen on Fig. 6, the error range of the predictions falling outside the central cone delimited by the whiskers remains important: Even if the overall performance of our method is better than the BADA method, it could still be improved for a number of specific flights. This suggests that learning several thrust laws for identified classes of climbs, instead of only one for all climbs, might improve the results again.

7.5. Assessing the quality of prediction from the error on the past trajectory

When using the prediction model in an operational context, the future trajectory is yet unknown, and \( e_{k}^{\text{(pred)}} \) is not available in real time. However, the model error on the \( n \) past and current points can be computed, and might give us some clues on the quality of the prediction on \( \Delta H_p \) and \( \Delta V_a \).

The expression of \( e_{k}^{\text{(past)}} \) is similar to the prediction error \( e_{k}^{\text{(pred)}} \), except that the thrust coefficients are computed using the observed values \( x_{k,i}^{\text{(obs)}} \) of the past \( n \) points instead of the predicted values \( x_{k,i}^{\text{(pred)}} \) of the \( p \) future points:

\[
e_{k}^{\text{(past)}} = \sqrt{\frac{\sum_{i=1}^{n} \left( \frac{\text{Power} \left( m_{k}^{\text{computed}} c_{k,i}^{\text{(obs)}} \right) - Q \left( x_{k,i}^{\text{(obs)}} \right) \right)^{2}}{n}}
\]

Fig. 8 plots the altitude error \( \Delta H_p \) and velocity error \( \Delta V_a \) against \( e_{k}^{\text{(past)}} \). We can observe a higher dispersion of the plots on the right-hand side of the figures. Globally, we have higher errors on the altitude and velocity when the model error on the past trajectory points \( e_{k}^{\text{(past)}} \) is high. Notice that this is not always true, however: There are a few trajectories with low errors on \( e_{k}^{\text{(past)}} \) that exhibit high errors on the altitude and velocity. Trajectories with low model error on the past points are just more likely to have low errors on the predicted altitude and velocity.

As an illustration, let us focus on the trajectories of case study 2 (CAS/Mach trajectories and computed ESF). On these trajectories, the median of \( e_{k}^{\text{(past)}} \) is 6.6 W/kg. If we compute the root mean square error of \( \Delta H_p \) on the trajectories for which \( e_{k}^{\text{(past)}} \) is inferior to the median, we obtain 532 ft. Similarly, if we compute the RMSE on the trajectories with \( e_{k}^{\text{(past)}} \) superior or equal to the median, we obtain 1044 ft.

To conclude this section, we have an empirical assessment of the quality of the prediction for each individual trajectory simply by considering the model error on the past points. If the model performs poorly on the past points, it is more likely to provide poor predictions on the future points as well.

8. Conclusion and future work

To conclude, we propose to improve the trajectory prediction accuracy performed by ground-based systems by inferring the mass and thrust law from observed data. These two parameters, mass and thrust, are crucial in the trajectory prediction.
of climbing aircraft. The aircraft mass is estimated from a few points of the past trajectory and the thrust law is learned from a training set of trajectory records. Although they might not be close to the actual mass and thrust law of each individual aircraft, the modeled mass and learned thrust are designed so as to improve the accuracy of the modeled energy rate.

The proposed mass estimation method takes advantage of the fact that the specific power is a polynomial function of the mass when using the BADA model of the drag and maximum climb thrust. Other models of the forces, more precise than BADA, might be compliant with our approach. For instance, the Enhanced Jet Performance Model (Kaiser et al., 2011) seems to be compliant with our analytical method.

Our method highly improves the trajectory prediction accuracy when compared with BADA model-based methods that use a single common mass per aircraft type or a standard thrust profile. When tested on real data, for a single aircraft type as a proof of concept, it improves the altitude prediction up to 40–50%. We also show that the model error on the past trajectory can provide an empirical assessment of the future prediction’s quality. From an operational point of view, the enhancement of the altitude prediction accuracy would certainly benefit to the air traffic controllers in the vertical separation task, and give more accurate inputs to the automated tools for conflict detection and resolution.

In future works, it could be interesting to try our method on Mode-S radar data, which is more accurate than Mode-C radar data, and for which the calibrated airspeed and Mach number of the equipped aircraft is available. In addition, we intend to compare our analytical mass estimation method with the adaptive method proposed in Schultz et al. (2012) on our set of real data.

Fig. 8. Relationship between $e_k^{\text{past}}$ and the altitude and velocity errors at the last point of the prediction.
There are several ways in which our method might be improved. For example, we might try to identify classes of trajectories from the historical data, and then learn several thrust laws (one per class) instead of only one. When predicting a new trajectory, the past points would then be used to select the most relevant thrust law. We could also study different parametrized functions modeling the thrust law: other functions, such as neural networks, might give better results than the simple polynomial functions used in the current paper. Finally, we also plan to compare our model-based approach that uses learned parameters with standard Machine Learning techniques (e.g. Neural Networks, Random forests, etc.) that would use the estimated mass and past observations as inputs.
