A B S T R A C T

Lead-free piezoelectric nanocomposites based on poly(ether ketone ketone) (PEKK) and sodium niobate (NaNbO₃) particles were elaborated. The presence of submicronic particles does not influence the thermal stability of the matrix so that no degradation phenomenon is observed before 500 °C. The conservative mechanical modulus G’ increases linearly with the NaNbO₃ fraction; this variation is well fitted by the Kerner model until 20 vol%. Such nanocomposites remain ductile. The polarizing field required for obtaining piezoelectric nanocomposites is 12 kV·mm⁻¹ i.e. analogous with the one used for poling bulk ceramic. The value of the piezoelectric coefficient (d33 = 0.2 pC·N⁻¹) for 20 vol% NaNbO₃ is consistent with the Furukawa’s model. This value is explained by the low PEKK permittivity. This low d33 is counterbalanced by the piezoelectric voltage constant (e33 = 103·10⁻¹³ Vm·N⁻¹) which is higher than the one of classical piezoelectric ceramic like PZT or BaTiO₃.

1. Introduction

The first extrinsic piezoelectric composite has been elaborated in 1976 by Furukawa. Micronic electroactive particles of lead zirconate titanate (PZT) have been dispersed in a polyepoxy matrix [1]. This kind of particles has been widely used subsequently, especially for applications of sensors and actuators due to a high Curie temperature and a high piezoelectric coefficient [2–6]. However, the recent legislation about lead toxicity [7] has highly stimulated the use of lead-free ceramic such as barium titanate (BaTiO₃) [8–12], potassium niobate (KNbO₃) [13–15], lithium niobate (LiNbO₃) [16,17], and sodium niobate (NaNbO₃) [13,18–20].

The interest of this study is the integration of the piezoelectric property using a lead-free piezoelectric ceramic in a structural polymer for aeronautical and space applications. Carponcin et al. [5] have studied the integration of PZT in poly(ether ether ketone) (PEEK). They showed that it was possible to disperse homogeneously electroactive particles in a high-performance thermoplastic matrix to bring it piezoelectric property. In this paper, the host matrix is the poly(ether ketone ketone) (PEKK), a high performance thermoplastic polymer also belonging to the poly(aryl ether ketone) (PAEK) family. PEEK has a melting temperature lower than PEEK making it less expensive for industrial processing. The lead-free selected electroactive ceramic was the NaNbO₃. It has a high Curie temperature (Tc) compatible with the matrix [21–23] and an interesting bulk piezoelectric coefficient (d33) [24,25]. The main challenge in piezoelectric composite processing is the polarization step. It is a critical step which is essential to obtain a piezoelectric material. It consists in applying an electric field (higher than the coercive field of the piezoelectric element) through the sample in order to orient the electric dipoles. Another advantage of NaNbO₃ is its low coercive field [26] and therefore it requires a low polarization field that limits the risk of breakdowns [27].

The present paper describes the synthesis and the characterization of NaNbO₃. Then, the elaboration and polarization protocol are presented. We will focus on the shape of NaNbO₃ particles on thermal stability, mechanical and electroactive properties of PEKK/NanNbO₃ nanocomposites.

2. Materials and methods

2.1. NaNbO₃ submicronic particles elaboration

NaNbO₃ particles were synthesized for the first time by Goh et al. [13] in 2003 using a hydrothermal synthesis. The structural evolution of NaNbO₃ during the reaction was studied more precisely by Zhu et al. [18]. First, fine powders aggregate to form irregular bars that grow into nanowires and finally submicronic particles. In this work, the David et al. [27] protocol, based on Goh’s one, has been used. Niobium pentoxide (Nb₂O₅) and concentrated sodium hydroxide (10 M)

http://dx.doi.org/10.1016/j.jnoncrysol.2016.12.030
were mixed in an autoclave and heated above 150 °C. The white compound obtained \((\text{Na}_{3}\text{Nb}_2\text{O}_9\cdot 2/3\text{H}_2\text{O})\) was filtered out, washed with de-ionized water and dried in an oven at 100 °C. NaNbO\(_3\) particles were obtained after an annealing at 600 °C for 6 h.

2.2. PEKK/NaNbO\(_3\) nanocomposite elaboration process

Ceramic particles were milled with a mortar in order to break any aggregates. They were dispersed in ethanol with ultrasound and mixed with the polymer powder. After ethanol evaporation, the PEKK/NaNbO\(_3\) nanocomposite powder was homogeneous. PEKK/NaNbO\(_3\) mix was processed using a twin screw extruder at 360 °C during 15 min at 30 rpm. Nanocomposites with different volume fractions were elaborated from 3% to 30% in volume fraction.

Fig. 1 represents a scanning electron microscopy (SEM) micro cut of PEKK/NaNbO\(_3\) 20 vol% sample. Particle dispersion in the polymer matrix was homogeneous at this scale. Dispersion quality is an important parameter to facilitate the polarization process and prevent from electrical breakdowns.

2.3. Polarization process

The polarization process consists in orienting electric dipoles to obtain a macroscopic piezoelectric effect [10]. The material was inserted under a high static electric field at a given isotherm. During the cooling, the electric field was maintained in order to fix the dipole orientation. Polarization temperature, electric field value and poling time were optimized.

The following Eq. (1) makes the link between the field really seen by the particles \(E_p\), the matrix and particle permittivities, \(\varepsilon_M\) and \(\varepsilon_p\) respectively, and the applied electric field \(E_{appl}\) [8].

\[
\frac{E_p}{E_{appl}} = \frac{3\varepsilon_M}{\varepsilon_p + 2\varepsilon_M} = \lambda_p \frac{E_{appl}}{E_{appl}}
\]

To optimize \(E_p\) (and therefore the polarization efficiency), the ratio between matrix and particle permittivity is crucial. A dynamic dielectric analysis was performed on the PEKK in order to determine the evolution of the matrix permittivity as a function of temperature. Above the dielectric manifestation of the glass transition \((T_g)\), \(\varepsilon_M\) increases; it is suitable for the polarization. Thus, the polarization was performed at a temperature higher than \(T_g\) \((T_{pol} \approx 180 °C)\) under an electric field higher than the coercive field \((E_{pol} \approx 12 \text{ kV/mm})\) during 15 min. To avoid breakdowns and to optimize the isotherm quality, samples were immersed in an oil bath. After the polarization process, nanocomposites were short-circuited during 24 h and the piezoelectric coefficient \((d_{33})\) was measured.

3. Experimental

Thermogravimetric analysis (TGA Q50 from TA instruments with an accuracy of \(\pm 1\) wt%) was performed under air atmosphere at 20 °C min\(^{-1}\) to measure the nanocomposites thermal stability and determine the experimental volume fraction of sodium niobate. The physical structure, as the glass transition, the crystallinity rate and the melting temperatures, was determined by differential scanning calorimetry (DSC) using a DSC7 from Perkin Elmer with a temperature accuracy of \(\pm 0.1 °C\) and an enthalpy accuracy of \(\pm 0.2 \text{ J·g}\(^{-1}\)\). The crystallinity rate was determined by normalizing the matrix fraction. To study nanocomposites mechanical properties, dynamical mechanical analysis (DMA, ARES) was performed in rectangular mode. The applied deformation and angular frequency were fixed at 0.1% and 1 rad·s\(^{-1}\) respectively. The particle morphology and the particle dispersion quality were observed using a scanning electron microscope (MEB-FEG JEOL JSM 7800F Prime) using secondary and backscattered electron detection. After the nanocomposites polarization (see “polarization process” section), the piezoelectric coefficient \((d_{33})\) was measured using a Piezometer system from Piezotest with frequency and force of 110 Hz and 0.25 N respectively.

4. Results

4.1. NaNbO\(_3\) analysis

Inset of Fig. 1 represents SEM image of NaNbO\(_3\) particles. They were cubic with a low aspect ratio. The particle size was about 1 μm. Due to a high Curie temperature \((T_c)\) and a weak modification of crystalline lattice parameters, conventional techniques as DSC or x-ray diffraction (DRX) could not be used to determine \(T_c\). A non-classical protocol has been developed: A ceramic disk was manufactured by spark plasma sintering (SPS) to limit the grain growth, polarized under a static field and annealed at different temperatures until Curie transition. The maximum \(d_{33}\) was measured at 34.5 pC·N\(^{-1}\) which is coherent with the literature [25,28].

Fig. 2 represents the \(d_{33}\) evolution as a function of annealing temperature. \(T_c\) was measured at 287 °C.

4.2. Thermal stability

Fig. 3 shows the weight loss as a function of temperature for nanocomposites with different NaNbO\(_3\) volume fraction. Under air
atmosphere, above 750 °C, PEKK was totally degraded. The weight residue corresponds directly to the weight fraction of NaNbO$_3$. The experimental volume fraction of NaNbO$_3$ is calculated from the residue at 900 °C. The degradation temperature ($T_d$) is measured at the peak maximum of the weight loss derivative curve. Inset of Fig. 3 represents the evolution of $T_d$ as a function of NaNbO$_3$ volume fraction. Until 6 vol%, $T_d$ is stable. It appears that for higher fractions, $T_d$ decreases when the fraction of NaNbO$_3$ increases.

4.3. Physical structure

Nanocomposites physical structure has been studied. Fig. 4 shows the evolution of the melting temperature and crystallinity ratio as a function of NaNbO$_3$ volume fraction. The melting temperature and the crystallinity ratio decrease linearly. Particles do not promote crystallinity and reduce the cohesion of the crystal. In addition, presence of particles does not change the glass transition temperature which means that NaNbO$_3$ crystals. In addition, presence of particles does not change the glass transition temperature which means that NaNbO$_3$ crystals. In addition, presence of particles does not change the glass transition temperature which means that NaNbO$_3$ crystals.

4.4. Mechanical properties

Fig. 5 shows the evolution of conservative $G'$ and dissipative $G''$ modulus of the neat PEKK over a wide range of temperature. $G'$ highlights 3 relaxation modes [29,30]: $\alpha$ mode at 165 °C is associated with the mechanical manifestation of the glass transition. $\beta$ mode between $-60$ °C and $0$ °C, with the oscillation of the aromatic rings around the main chain and finally, the localized $\gamma$ mode between $-130$ °C and $-60$ °C highlights the interaction between ketone functions and absorbed water.

The evolution of the vitreous modulus of PEKK/NaNbO$_3$ nanocomposites is presented in Fig. 6 as a function of temperature for different volume fraction of NaNbO$_3$. The value of the vitreous plateau increases with the introduction of NaNbO$_3$, from 1.5 GPa to 3.7 GPa at 20 °C. Inset of Fig. 6 represents $G'$ measured at $T_g$-50 °C as a function of NaNbO$_3$ volume fraction.

It increases linearly until 20 vol%. To explain the critical increase of $G'$ for the last nanocomposite experimental data were fitted with the Kerner model (solid line). It is based on the hypothesis that spherical particles (or particles with a low aspect ratio) without interaction, are randomly dispersed in the matrix. Nanocomposite conservative modulus is given by the Eq. (2) [31]:

$$G_c = G_m \left( \left( \frac{\phi_{\text{d}}}{\theta_{\text{d}}} \right) \frac{d \phi_{\text{d}}}{d \phi_{\text{d}}} + \frac{\left( 1 - \phi_{\text{d}} \right)}{\left( 1 - \phi_{\text{d}} \right)} \right)$$

$$G_m = \left( \frac{\left( 7 - 5 \phi_{\text{m}} \right) G_{\text{m}} + \left( 8 - 10 \phi_{\text{m}} \right) G_{\text{p}}}{\left( 7 - 5 \phi_{\text{m}} \right) G_{\text{m}} + \left( 8 - 10 \phi_{\text{m}} \right) G_{\text{p}}} \right) \frac{1}{15 \left( 1 - \phi_{\text{m}} \right)}$$

4.4. Mechanical properties

Fig. 5. Evolution of the conservative $G'$ (▲) and dissipative $G''$ (○) modulus of PEKK versus temperature.

Fig. 6. Real part of the shear modulus (■) versus temperature of PEKK and PEKK/NaNbO$_3$: (■) PEKK, (○) PEKK/NaNbO$_3$ 4 vol%, (▲) PEKK/NaNbO$_3$ 6 vol%, (●) PEKK/NaNbO$_3$ 9 vol%, (▲) PEKK/NaNbO$_3$ 11 vol%, (●) PEKK/NaNbO$_3$ 10 vol%, (○) PEKK/NaNbO$_3$ 20 vol%, (●) PEKK/NaNbO$_3$ 30 vol%. In the inset: value of the vitreous plateau measured at $T_g$-50 °C versus vol%. The solid line represents the fit of experimental data with the Kerner model.
where \( G_s, G_m \) and \( G_p \) are respectively the shear modulus of nanocomposites, matrix and particles, \( \nu_m \) is the Poisson coefficient and \( \phi \) is the volume fraction of particles.

Until 20 vol\% experimental data are fitted well with this model. Thus, hypotheses are verified. For the nanocomposite with 30 vol\% of NaNbO\(_3\), the experimental mechanical values depart from the model prediction.

The evolution of the dissipative modulus \( G'' \) of PEKK/NaNbO\(_3\) nanocomposites as a function of temperature is presented in Fig. 7 for different volume fraction of NaNbO\(_3\). The area under the curve (noted as \( \alpha_{\text{PEKK}} \) and \( \alpha_{\text{PEKK/NaNbO}} \) for PEKK and its nanocomposites respectively) represents the energy dissipated by the polymer matrix due to the viscoelastic relaxation. Inset of Fig. 7 represents the specific energy loss normalized by the matrix fraction as a function of NaNbO\(_3\) volume fraction. Presence of ceramic particles leads to an increase of the dissipated energy. The same shift is observed for \( \beta \) and \( \gamma \) modes at the same temperatures.

4.5. Piezoelectric properties

\( d_{33} \) coefficient of nanocomposites was measured 24 h after the polarization step. Fig. 8a) represents the evolution of \( d_{33} \) as a function of NaNbO\(_3\) volume fraction. Experimental data were fitted with the Furukawa’s model [2] (solid line in Fig. 8a) according to the following Eq. (3):

\[
d_{33} = \phi d_{33\text{incl}}
\]

where \( d_{33} \) is the piezoelectric coefficient of nanocomposites, \( \phi \) the volume fraction of NaNbO\(_3\), \( E_L \) the local field applied [8] and \( d_{33\text{incl}} \) the intrinsic piezoelectric coefficient of bulk NaNbO\(_3\).

This model considers a 2-phases system composed of a non-piezoelectric continuous phase where piezoelectric particles are randomly dispersed.

From 8 vol\%, the variation of \( d_{33} \) is quasi-linear and experimental data are closed to the expected values. Particles are well dispersed into the matrix until 20 vol\%.

In addition to the \( d_{33} \), the piezoelectric voltage constant \( g_{33} \) is another piezoelectric parameter given by the following Eq. (4) [27]:

\[
g_{33} = \frac{d_{33}}{\varepsilon_m}
\]

For bulk piezoelectric ceramic, \( d_{33} \) and \( \varepsilon_m \) are both high. For organic polymer where piezoelectric ceramics are dispersed, \( d_{33} \) is low. But it is counterbalanced by a very low matrix permittivity. Fig. 8b) shows the evolution of \( g_{33} \) with the NaNbO\(_3\) volume fraction. The low matrix permittivity leads to a high value of \( g_{33} \) (\( g_{33} \) (PEKK/30 vol\% NaNbO\(_3\) = 104·10\(^{-3}\) Vm\(^{-1}\) N\(^{-1}\)).

5. Discussion

5.1. Curie temperature measurement

Literature reports values from 180 °C to 370 °C for the \( T_c \) of NaNbO\(_3\). The discrepancy obtained could be explained by poly crystallinity and/or particle size. Most of the time, \( T_c \) measurements were performed on mono crystals [21]. Hydrothermal synthesis tends to promote poly crystals. Furthermore, Moure et al. [22] show the influence of particle size on \( T_c \). Particles with size higher than 1 \( \mu \)m have a \( T_c \) at 370 °C. For particles with a size between 200 and 400 nm, \( T_c \) ranges from 310 °C to 330 °C and finally for particle size lower than 70 nm, \( T_c \) is measured at 180 °C. In this work, a size distribution probably exists and could explain the low value of \( T_c \).

5.2. Conservative and dissipative modulus

For the nanocomposite with 30 vol\% of NaNbO\(_3\), experimental data of conservative modulus depart from the model prediction (Kerner model). This is due to a change of the composite connectivity from 0–3 to 3–3 [22] that probably suppose a contact between particles and therefore critical modifications of the mechanical properties.

The increase of the dissipated energy (calculated from the area under the dissipative modulus) with the introduction of particles could be due to a friction phenomenon called “stick slip” at the interface between stiff particles and soft matrix [33]. In addition, it is interesting...
To note that mode temperatures are not modified by the introduction of NaNbO₃ so the molecular mobility is unchanged by the presence of particles.

5.3. Piezoelectric coefficients

For the PEEK/Nan NbO₃ 30 vol%, experimental data diverge from the Furukawa model. The change of connectivity also affects the piezoelectric property. However, the $d_{33}$ values obtained are low. Particle and matrix permittivities have a strong influence on the polarization efficiency. On the one hand, a PVD/20 vol% NaNbO₃ nanocomposite was elaborated with the same process and polarized. Its $d_{33}$ is higher (3.95 pC·N⁻¹) [see (Fig. 8 a)] due to the higher permittivity of the PVDF (12 for PVD, 2.7 for PEKK at RT). This value is coherent with the $d_{33}$ value predicted by Furukawa’s theoretical model. On the other hand, the influence of the particle intrinsic $d_{33}$ is important. To give an example PEKK/PZT 30 vol% nanocomposite has a $d_{33}$ of 1.95 pC·N⁻¹ [5] due to a high $d_{33}$ of PZT (240 pC·N⁻¹) [34]. Nevertheless, $g_{33}(\text{PEKK}/30\text{vol% NaNbO}_3)$ is higher than common piezoelectric ceramics like $g_{33}(\text{BaTiO}_3) = 11.10^{-3} \text{Vm}^{-1}\text{N}^{-1}$ or PZT ($g_{33}(\text{PZT}) = 52.10^{-3} \text{Vm}^{-1}\text{N}^{-1}$).

6. Conclusion

Piezoelectric nanocomposites were elaborated using a high performance thermostable thermoplastic polymer and a lead-free piezoelectric ceramic. Submicron NaNbO₃ was synthesized via a hydrothermal synthesis. The dispersion process leads to a good dispersion of particles in the PEKK. Particles do not influence the thermal stability of matrix: no degradation is observed before 500 °C. Melting temperature and crystallinity rate decreases with the NaNbO₃ volume fraction. As for mechanical properties, the value of the vitreous plateau generates an evident the thermal stability of matrix: no degradation is observed before 500 °C. Melting temperature and crystallinity rate decreases with the NaNbO₃ volume fraction. As for mechanical properties, the value of the vitreous plateau generates an evident increase of the nanocomposite rigidity. We observe a stick-slip phenomenon that increases the dissipated energy related to the viscoelastic relaxation when the particle fraction increases. Polarization is a critical step due to high temperature and high electric field required. The piezoelectric coefficient increases with the ceramic particles content but remains low due to low matrix permittivity. For other applications, the $d_{33}$ could be improved with matrix of higher permittivity. It is important to note that the piezoelectric voltage constant $g_{33}$ is higher than for common inorganic piezoelectric ceramic like PZT or BaTiO₃.

Acknowledgments

These results were obtained under the research project “COMPINNOVT” at the IRT Saint Exupéry. We thank the industrial and academic members of the IRT who supported this project through their contributions, both financial and in terms of specific knowledge:

- Industrial members: AIRBUS OPERATIONS, AIRBUS DEFENCE & SPACE, AIRBUS HELICOPTERS, AIRBUS GROUP INNOVATIONS and THALES ALENIA SPACE.
- Academic members: CIRIMAT, ISAE, ICA, IMRCP, UPS and CNRS.
