Abstract

Detailed sensitivity numerical studies have shown that the mesh cell-size may have a drastic effect on the modelling of circulating fluidized bed. Typically the cell-size must be of the order of few particle diameters to predict accurately the dynamical behaviour of a fluidized bed. Then the Euler-Euler numerical simulations of industrial processes are generally performed with grids too coarse to allow the prediction of the local segregation effects. A filtered approach is developed where the unknown terms, called sub-grid contributions, have to be modelled. Highly resolved simulations are used to develop the model. They consist of Euler-Euler simulations with grid refinement up to reach a mesh independent solution. Then spatial filters can be applied in order to measure each sub-grid contribution appearing in the theoretical filtered approach. Such kind of numerical simulation is very expensive and is restricted to very simple configurations. In the present study, highly resolved simulations are performed to investigate the sub-grid contributions in case of a binary particle mixture in a periodic circulating gas-solid fluidized bed. A budget analysis is carried out in order to understand and model the effect of sub-grid contribution on the hydrodynamic of polydisperse gas-solid circulating fluidized bed.

Keywords: gas-solid flow, circulating fluidized bed, polydisperse mixture, filtered approach, subgrid drag force, particle-particle collision

1. Introduction

Gas-solid reacting circulating fluidized beds are used in many industrial processes such as fluid catalytic cracking (FCC) in petroleum refineries or fossil combustion in power plants. Modelling of gas-particle flows, using the Two-Fluid Model (TFM) approach closed by the Kinetic Theory of Granular Flows (KTGF) is well established [3, 5, 11]. However, for A-type particles, according to Geldart’s classification, the numerical simulations with coarse grids fail to predict the behaviour of the solid phase due to the inaccurate prediction of the solid clusters [2, 13, 14]. For instance, Parmentier et al. [14] shows that neglecting the small structures in dense fluidized bed simulation leads to an overestimation of the bed height. According to Ozcel et al. [13] and Andreux et al. [1] the insufficient mesh refinement leads to underestimate the vertical solid mixing and residence time in circulating fluidized bed. In addition, in bi-solid circulating fluidized bed, Batrak et al. [3] show that the “coarse mesh” simulation leads to underestimate the momentum coupling between particle species with large density ratio and, consequently, the entrainment rate of the coarse particles by the small ones. The modelling strategy consists in splitting the local instantaneous variables in resolved and subgrid contributions. The corresponding governing equations are obtained by filtering the particle kinetic moment transport equations leading to unknown subgrid terms which need to be modelled in terms of the computed resolved variables. The first step is the budget analysis of the filtered transport equation and the evaluation of the resolved and sub-grid contributions of each terms. This step highlights which term(s) need(s) to be modelled, leading to the subgrid modelling step to account accurately for the effect of the small scale structures in the filtered equations. For monodisperse simulations, the drag force is overestimated by the resolved contribution and may lead to wrong predictions of the global hydrodynamic behaviour [15]. Several sub-grid models have been proposed by Ozcel et al. [13], Parmentier et al. [15] to take into account the effect of the unpredicted solid cluster on filtered fluid-particle drag force modelling. For polydisperse simulations, the particle-particle momentum exchange has also to be studied. Holloway [6] focus on the need for sub-grid scale models for coarse-grid simulation of a binary gas-particle flow. The filtering of highly resolved simulation of bidisperse gas-particle flows shows that filtered constitutive relations also need to be developed for polydisperse systems to settle the difference between coarse grid and fine grid simulations. Ozcel et al. [13] focus on the filtered momentum equation balance analysis in a bisolid fluidized bed, showing that subgrid models are needed for both the fluid-particle and particle-particle mean momentum transfer terms.

This article focus on the analysis of highly resolved simulations of bidisperse flow in a 3D periodic circulating fluidized bed. The resolved and unresolved contributions are compared for all the terms of the momentum and the kinetic agitation equations.

2. Mathematical modelling approach

The modelling approach is based on the Euler-Euler model, in which phases are treated as continuous interpenetrated media. The mass, the momentum and the energy Eulerian transport equations are solved for each phase and coupled by interphase transfer terms. The mass transport equation writes:

$$\frac{\partial}{\partial t} \rho_k \alpha_k + \frac{\partial}{\partial x_j} \rho_k \alpha_k U_{k,j} = 0,$$

with $\rho_k$ the density of the $k$th phase and $U_{k,j}$ the $j$th component of the velocity.

The momentum transport equation writes:

$$\alpha_k \rho_k \left[ \frac{\partial U_{k,i}}{\partial t} + U_{k,j} \frac{\partial U_{k,j}}{\partial x_j} \right] = - \alpha_k \frac{\partial P_g}{\partial x_i} + \alpha_k \rho_k g_i + \sum_{k'=\rho, p} \sum_{k''=0} \delta_{k,k''} I_{k',k''},$$

In the equation 2, the first and second term on the right-hand-side are the pressure gradient, with $P_g$ mean gas pressure, and the
gravity contributions with, $g_i$ the $i^{th}$ component of the gravity, respectively. The third term on the right-hand-side represents the momentum transfer (without the mean gas pressure contribution). This term takes into account two mechanisms: the friction of the fluid on particles (gas ↔ particles transfer) and the exchange of momentum by collisions (particles ↔ particles transfer). The effective stress tensor has two components

$$
\Sigma_{k,ij} = \alpha_k p_k (u'_{k,j} u'_{k,i})_p + \Theta_{k,ij}
$$

(3)

where $\langle u'_{k,j} u'_{k,i} \rangle_p$ are the Reynolds stress tensor ($u'_j$ is the phase velocity fluctuation) and $\Theta_{k,ij}$ is the viscous stress tensor for the gas and the collisional stress tensor for particles. The term $F_{k,i}$ is a constant in the whole domain (as hereinafter defined). Hence, this term will not appear in the transport equation of the kinetic agitation $q_p^2$ and is independent of the filter width.

2.1. Gas-particle momentum transfer

The momentum transfer between gas and particles is done taking into account only the drag and Archimedes’ pressure gradient force. Then, the fluid-particle transfer term in (2) is written:

$$
I_{g\rightarrow p,i} = \frac{\alpha_p p_p}{\tau_{fp}} (U_{p,i} - U_{g,i})
$$

(4)

The term satisfies $I_{g\rightarrow p,i} = -I_{p\rightarrow g,i}$. The particle relaxation timescale $\tau_{fp}$ is written as a function of the drag coefficient:

$$
\frac{1}{\tau_{fp}} = \frac{3}{\rho_g} \frac{\mu}{d_p} C_d
$$

(5)

The drag coefficient is calculated using the Wen and Yu correlation [17]. As Simonin et al. [16] show that the this model provides results close to the bidisperse LBM data and drag force correlations from the literature,

$$
C_d = \frac{2}{Re_p} \left[1 + 0.15Re_p^{0.687}\alpha_g^{1.7}\right]
$$

(6)

The particle Reynolds number is written as $Re_p = \frac{\alpha_p p_p \langle |v'_p| \rangle d_p}{\mu_g}$.

2.2. Particle-particle momentum transfer

According to Gourdel et al. [4], the particle-particle momentum transfer term is written, \n
$$
I_{p\rightarrow q,i} = \frac{m_p m_q}{m_p + m_q} \frac{1 + e_{pq} n_q}{2} \tau_{pq} H_i(z) (U_{p,i} - U_{q,i})
$$

(7)

where $m_p$ and $m_q$ are the masses of particles $p$ and $q$, $e_{pq}$ the normal restitution coefficient of $p - q$ collision, $\tau_{pq}$ is characteristic time scale between two collisions of any $p$-particle with the $q$-particles and writes,

$$
\frac{1}{\tau_{pq}} = g_0 n_q \tau_{dpq} b_r
$$

(8)

with $\tau_{dpq}$ the distance between particle centers when the collision takes place $\tau_{dpq} = (d_p + d_q)/2$ and $g_0$ the mean relative velocity of impact of particles of different types, written as:

$$
g_r = \sqrt{\frac{16}{3}} \left[ \frac{16}{3} \bar{q}_r + V_{pq,i} V_{pq,i} \right]
$$

(9)

$V_{pq,i}$ the relative velocity between particles is written: $V_{pq,i} = U_{p,i} - U_{q,i}$. $\bar{q}_r$ is the mean relative agitation of particles $q_i = \frac{1}{2} (q_p^2 + q_q^2)$ and $g_0$ the radial pair distribution function is calculated using [8],

$$
g_0 = \left[1 - \frac{\alpha_s}{\alpha_{max}} \right]^{2.5 \alpha_{max}} \quad \text{if} \quad \alpha_s < \alpha_{max}^*
$$

(10)

with $\alpha_s$ the whole solid volume fraction. $H_i(z)$ is a function dealing with the change from a regime of collision controlled by the slip between particles to a regime controlled by the relative agitation which is approximated by [3],

$$
H_i(z) = \frac{8 + 3z}{6 + 3z}
$$

(11)

For $z \rightarrow 0$ the inter-species collisions are driven by the relative agitation. For $z \rightarrow +\infty$ the collisions are controlled by the mean particle-particle relative velocity,

$$
z = \frac{V_{pq} V_{pq,i}}{\epsilon_{pq}}
$$

(12)

2.3. Particle random kinetic energy modelling

The solid agitation is calculated using $q_p^2$ transport equation and viscosity model assumption developed in the frame of kinetic theory of polydisperse particle mixture accounting for the mean and fluctuant drag force effects [3, 11]:

$$
\alpha_p \rho_p \left[ \frac{\partial q_p^2}{\partial t} + U_{p,j} \frac{\partial q_p^2}{\partial x_j} \right] = \frac{\partial}{\partial x_j} \left[ \alpha_p \rho_p \left( K_{p,kin} + K_{p,cout} \right) \frac{\partial q_p^2}{\partial x_j} \right]
$$

$$
+ \Pi_p + \epsilon_f
$$

(13)

In the Eqn.(13) the first term on the right-hand-side represents the kinetic diffusivity, the second term the energy production by velocity gradient,

$$
\Pi_p = -\sum_{p,i,j} \frac{\partial U_{p,i}}{\partial x_j}
$$

(14)

The third term is the transfer of kinetic energy between gas and particle. It takes into account friction of the solid phase with the gas phase which is assumed to be laminar,

$$
\epsilon_f = -\epsilon_{pq} \frac{\alpha_p \rho_g}{\tau_{fp}} q_p^2
$$

(15)

The fourth term is the loss of energy due to inelastic collisions which is written:

$$
\epsilon_{pq} = -m_p \left( \frac{2m_q}{m_p + m_q} \right)^2 \frac{1 - e_{pq}^2}{4} \frac{n_p}{\tau_{pq}} \frac{n_q}{2} (q_p^2 + q_q^2)
$$

(16)

The last term is the transfer of kinetic energy between species and production by slip velocity between particles,

$$
\chi_{pq} = P_{pq} + T_{pq}
$$

(17)

$$
P_{pq} = \frac{m_p m_q^2}{m_p + m_q} \left( \frac{1 + e_{pq} n_p}{\tau_{pq}} \right) \frac{n_q}{2} (q_p^2 - q_q^2) H_i(z)
$$

(18)

$$
T_{pq} = -\frac{m_p}{m_p + m_q} \left( \frac{1 + e_{pq} n_p}{\tau_{pq}} \right) \frac{n_q}{2} \left[ 8 m_q q_p^2 - m_p q_q^2 \right] \frac{3}{m_p + m_q}
$$

(19)
3. Numerical simulation overview

Using the equations written below, several simulations of polydisperse and reactive flows were already conducted [7, 4]. Agrawal et al. [2] highlighted effects of small structures on polydisperse simulations. In this study, gas-particles flows are simulated in a 3D periodical Circulating Fluidized Bed (CFB). The geometry, used previously by Ozel et al. [13], has a squared-section of 0.0275 m and a length of 0.22 m and is shown by Fig. 1.

Three dimensional numerical simulations of fluidized bed have been carried out using an Eulerian n-fluid modeling approach for gas-solid turbulent polydisperse flows developed and implemented by IMFT (Institut de Mécanique des Fluides de Toulouse). NEPTUNE_CFD is a multiphase flow software developed in the framework of the NEPTUNE project, financially supported by CEA (Commissariat à l’Energie Atomique), EDF (Electricité de France), IRSN (Institut de Radioprotection et de Sécurité Nucléaire) and AREVA_NP. The numerical solver has been developed for High Performance Computing[9, 10].

4. Budget analysis of the filtered particulate momentum equation

Mesh independent results are used for the budget analysis of the filtered particle momentum and agitation equations. The aim of the analysis is to examine the contribution of sub-grid terms obtained after filtering equations. Different filter widths \( \Delta \) have been applied to the results. The spatial filter applied is defined as:

\[
G(x - r) = \left\{ \begin{array}{ll}
\frac{1}{\Delta} & \max(x_i - r_i) \leq \frac{x}{\Delta} \\
0 & \text{otherwise}
\end{array} \right.
\]  

where \( G \) is a weight function which satisfies \( \int G(x)dx = 1 \). The filtered phase volume fraction is defined as,

\[
\bar{\alpha}_k(x, t) = \int \int \int G(x - r)\alpha_k(x, t)G(x - r)dr
\]

Filtered phase velocities are defined according to,

\[
\bar{U}_p(x, t) = \frac{1}{\bar{\alpha}_p}\int \int \int G(x - r)\alpha_p(x, t)U_p(x, t)dr
\]

To obtain filtered values, especially solid volume fractions, independent of the filters widths, the domain studied is restricted to the interior of the periodic box and the regions near the walls are not taken into account, the distance between the wall and the domain taken studied is equal to \( \frac{1}{6}L \).

4.1. Particle momentum filtered transport equation

The filter is applied to the momentum equation (Eqn. (2)) and the filtered terms are decomposed into resolved and sub-grid terms. Additional terms arise in Eqn. (26) due to the filtering, the sub-grid contributions, noted \( f^{sgs} \). After filtering and averaging each term over space and time, the momentum equation becomes:

\[
\frac{\partial}{\partial t} \langle \rho_p \bar{U}_k \rangle + \frac{\partial}{\partial x_j} \sum_{p} \langle \rho_p \bar{U}_k \bar{U}_j \rangle - \sum_{p} \langle \rho_p \bar{U}_k \bar{U}_j \rangle = - \frac{M}{\Delta t} \sum_k m_k g_k - \sum_k m_k g_k
\]

Figure 1: Sketch of the computational domain

Agrawal et al. [2] studied three different boundary conditions for the solid phase: free-slip, partial-slip (definition of a particle-wall restitution coefficient is needed) and no-slip. Meso-scale structures were observed in the three cases. In the case studied, the boundary conditions imposed at walls are no-slip for the gas and free-slip for the solid phase. Three meshes have been studied and the most refined mesh with a mesh size equal to 2.9 \cdot 10^{-3} m (about 7.1 \cdot 10^6 mesh-cells) will be used for the budget analysis. For the case studied in the paper, the velocity fields are set initially to zero for all phases. The movement of the fluid is opposite to the gravity due to the pressure gradient imposed. The gas pressure is defined in a similar way than Agrawal et al. [2]. To ensure the periodicity of the simulation, it is necessary to maintain momentum in the whole domain at each time step. Considering the periodicity and the independence of the filters widths, the domain studied is restricted to the interior of the periodic box and the regions near the walls is shown by Fig. 1.
The temporal averaged is represented by $\overline{T}$ and is done on 3.5s. $f^{\text{sgs}}$ is defined as the difference between filtered and resolved contributions. A term calculated by using filtered values corresponds to a resolved contribution noted with the subscript $f^{\text{res}}$. For instance, $\psi_{p,i}^{\text{sgs}}$ represents the sub-grid contribution of the correlation between fluctuations of the volume fractions of phases and gas pressure:

$$\psi_{p,i}^{\text{sgs}} = \alpha_p \frac{\partial P_i}{\partial x_i} - \alpha_p \frac{\partial P_i}{\partial x_j}.$$

(27)

The subgrid contributions of the particle kinetic stress, $\Sigma^{\text{sgs}}_{p,i}$, the gas-particle momentum transfer, $I^p_{p,i}^{\text{sgs}}$, and particle-particle momentum transfer, $I_{p,i}^{\text{sgs}}$, are calculated similarly. The resolved gas-particle momentum transfer, particle-particle momentum transfer, pressure gradient contributions normalized by the gravity term are presented by Fig. 2 and 3 for small and large particles. For the small particles the main contribution is the drag force and for the large particles, it is the inter-particle momentum transfer. For both classes of particles, the resolved and sub-grid contributions can be neglected for the pressure gradient.

Furthermore, the sub-grid gas-particle momentum transfer increases with the filter width, in agreement with the work of Ozel et al. [12]. The filtered gas-momentum transfer is overestimated by the resolved contribution and the subgrid contribution must be accounted for to correct this effect. The trend is similar for the particle-particle momentum transfer with an overestimation of the inter-species momentum transfer effect by the resolved contributions. So this effect should be accounted for by modelling the subgrid contribution. Therefore, this result may look in contradiction with coarse mesh simulation of bi-disperse gas-solid fluidized beds [3] where the inter-particle momentum transfer effects are underestimated. The probable explanation of this contradictory result is that the resolved collision frequency, and the corresponding momentum transfer, are underestimated due to a drastic underestimation of the resolved random particle kinetic energy in coarse mesh simulations. Then it is crucial to analyse the corresponding filtered equation to identify the missing contribution which should be accounted for to have a better prediction of the random particle kinetic energy.

As for the pressure gradient, the sub-grid contributions of the kinetic stress and of the particle phase velocity fluctuations are negligible for both classes of particles.

4.2. Particle random kinetic energy filtered transport equation

The filtering process is applied to the random kinetic energy equation (13) with the resolved and subgrid contributions. The filtered energy balance can be written as:

$$\langle \alpha_p \rho_p U_{p,k} \frac{\partial \rho_d}{\partial x_j} \rangle = \left[ \frac{\partial}{\partial x_j} \left( \alpha_p \rho_p \left( K_{p,k}^{\text{res}} + K_{p,col}^{\text{res}} \right) \frac{\partial \rho_d}{\partial x_j} \right) \right]_{\text{comp}} + \left( \frac{\partial}{\partial x_j} D_{p}^{\gamma_p} \right) - \left( \Pi_{p}^{\text{sgs}} \right) - \left( \epsilon_{p}^{\text{sgs}} \right) + \left( \sum_{q} P_{p,q}^{\text{res}} \right) + \left( \sum_{q} P_{p,q}^{\text{sgs}} \right) + \left( \sum_{q} T_{p,q}^{\text{res}} \right) + \left( \sum_{q} T_{p,q}^{\text{sgs}} \right) - \left( \frac{\partial}{\partial x_j} \alpha_p \rho_p Q_{p,j}^{\gamma_p} \right)$$

(28)
The mean velocity and diffusive transport and the sub-grid kinetic energy flux are negligible compared to the others contributions and the study will focus on others contributions.

Figures 4 and 5 show the production by gradient, the dissipation by friction with the gas phase, the sum of all the contributions linked to collisions, the kinetic diffusivity according to the filter size. Figures 6 and 7 show the dissipation by inelastic collision, the production by relative velocity, the transfer by collisions as functions of the filter width. For the small particles, Figure 4 shows that the production by the mean velocity gradient is mostly in equilibrium with the dissipation by the fluid-particle drag and, secondarily, by inter-particle collision effects. The resolved production underestimates the filtered ones and should be completed by a subgrid contribution which increases with the filtered width. In contrast, the resolved collision term underestimates the filtered one while the subgrid contribution to the dissipation by drag is negligible. Figure 6 shows the separate contributions of the collision terms with \( \epsilon_{pg} \), the inelastic dissipation, \( P_{p} \), the production by the mean relative particle motion, and \( T_{p} \), the kinetic energy transfer between particle species. We can notice that the resolved kinetic energy transfer between particle species and the inelastic dissipation rate are nearly independent of the mesh size implying that the subgrid contributions are negligible. In contrast, the filtered production by the mean relative velocity between particle species is overestimated by the resolved one and the sub-grid effect must be accounted for in the filtered modelling approach. Figure 5 shows that the budget of the coarse particle \( \Delta = 150 \mu m \) random filtered random kinetic energy equation is dominated by the equilibrium between mean velocity production and dissipation by the collision effect, while the drag dissipation effect looks nearly negligible. The resolved production is also decreasing with the filter width and the collision effect is overestimated by the resolved contribution. Figure 7 shows the separate contributions of the filtered collision term which confirms that the subgrid effect is measurable mostly for the production term due to the mean relative velocity between particle species.

5. Conclusion

Meso-scale structures are formed in the circulating fluidized bed and they can be resolved in the frame of Euler-Euler approach, based on kinetic theory of polydisperse granular flows, on high resolution computational grid. However, simulations with coarse meshes cannot account for these structures accurately and this may lead to very poor predictions of bed hydrodynamics for very small particle to mesh size ratio. For mono-dispersed gas-solid flow, Ozel et al. [13], and Parmentier et al. [14] analyse the effect of the small structures on the simulations for circulating fluidized bed and dense fluidised beds, respectively. In this study, we have investigated effects of unresolved structures on resolved field for gas-solid bidisperse flow. We first obtained mesh-independent results of gas-solid in a 3D periodic circulating fluidized bed. A filtering procedure was performed on particular momentum and kinetic agitation equations. Additional resolved and subgrid terms appearing with the filtering procedure are investigated by budget analysis in order to identify the main subgrid contributions. The analysis of the filtered momentum equation shows that the resolved fluid-particle drag and particle-particle collision are overestimating the momentum transfer effects and must be corrected by subgrid modelled contributions. The analysis of the budget of the filtered random kinetic energy shows that the resolved production by the mean shear and by the mean particle relative motion are overestimating the filtered ones. So new subgrid models have to be developed for these two terms while the subgrid contributions due to drag force or inelastic collision dissipations and to inter-particle redistribution are negligible.
