A B S T R A C T

In this paper, the design of a “low cost full passive structure” of wind turbine system without active electronic part (power and control) is investigated. The efficiency of such device can be obtained only if the design parameters are mutually adapted through an optimization design approach. For this purpose, sizing and simulating models are developed to characterize the behavior and the efficiency of the wind turbine system. A model simplification approach is presented, allowing the reduction of computational times and the investigation of multiple Pareto-optimal solutions with a multiobjective genetic algorithm. Results show that the optimized wind turbine configurations are capable of matching very closely the behavior of active wind turbine systems which operate at optimal wind powers by using a MPPT control device.

1. Introduction

Close to high power wind turbines for onshore or offshore applications, small wind systems represent an interesting target for applications such as rural electrification and autonomous energy production networks for water pumping, desalination. Optimizing energy efficiency generally leads to adapt the load impedance and consequently the speed of the generator with the wind turbine operating conditions. Many active structures have been thus proposed [1–15] to allow tracking the maximum power operation through corresponding MPPT strategies.

However, for such application frame, the system cost has to be drastically minimized for instance by simplifying the structure with PM synchronous generator feeding a diode rectifier associated with a battery bus. For grid connected applications, impedance adaptation can be obtained through the grid inverter as in [13]. In this paper we propose a very “low cost structure” for remote applications without active control unit and with a minimum number of sensors. In fact, for such device a “natural” impedance adaptation can be achieved with the passive structure by optimizing the accordance between system parameters [15–18].

The paper is organized as follows. In Section 2, the architecture of the passive wind turbine system considered in this study is described and the mechanical behavior of the turbine is given. In Sections 3 and 4 the sizing models of the wind turbine generator and of the diode rectifier are developed, considering multiple viewpoints (geometrical features, thermal and electrical characteristics). Section 5 is dedicated to the models simulating the wind turbine systems. In particular, a model simplification approach is presented in order to obtain reduced models with low computational times and acceptable accuracy. Finally, the multiobjective optimization of passive wind turbine generators is investigated in Section 6. The complete optimization process is developed and the Pareto-optimal configurations obtained for a particular wind cycle are presented and analyzed considering different standpoints (wind extraction, energetic behavior, model sensitivity).

2. The small passive wind turbine system

2.1. The wind turbine structure

In order to minimize the system cost and to maximize its reliability, the “full passive” architecture of Fig. 1 is put forward. This structure is mainly dedicated to small scale wind turbines, particularly for remote systems. A battery bank is then associated to a passive diode rectifier to allow an autonomous system operation. A minimum number of sensors and no control unit is required in this “low cost” structure.

The main drawback of this structure is its poor energetic efficiency. However, it will be shown in the following sections, that it can be clearly improved if some design parameters are properly chosen, through an integrated optimal design approach similar to that presented in [17,19,26].
2.2. The wind turbine model

A Savonius vertical axis wind turbine of radius \( R = 0.5 \) m and height \( H = 2 \) m is considered as case study (see Fig. 2).

It has to be noticed that the proposed structure and the corresponding design process could be applied for any vertical or horizontal axis turbines. However, due to its bell shape power coefficient \( (C_p) \), the Savonius turbine requires to conveniently adapt the shaft speed with respect to wind levels. Thus, it is certainly a good application to present the efficiency of the optimization based design of the passive structure. In this particular case study, the power coefficient \( (C_p) \) is defined by the following empirical relation:

\[
C_p = \frac{-0.1299\lambda^3 - 0.1168\lambda^2 + 0.4540\lambda}{\lambda^3}
\]

where \( \lambda \) is the tip speed ratio, depending on the turbine rotational speed \( \Omega \) and the wind speed \( V_W \).

\[
\lambda = \frac{R\Omega}{V_W}
\]

The associated wind turbine power is defined as [20]:

\[
P_{WT} = \frac{1}{2}C_p\rho A V_W^3
\]

where \( \rho \) denotes the air density \((\rho \approx 1.2 \text{ kg m}^{-3})\) and \( A \) represents the swept rotor area. It is noticed that the wind power is maximum when the power coefficient is maximum \((C_p = 0.22)\), i.e. for the optimal tip speed ratio \((\lambda^* \approx 0.82)\). For various wind speed values, the rotor speed should be adapted to operate close to the optimal tip speed ratio.

---

**Nomenclature**

**Wind turbine variables**

- \( C_p \) wind turbine power coefficient
- \( \Omega \) wind turbine rotational speed
- \( T_{WT} \) wind turbine torque
- \( \lambda \) tip speed ratio
- \( A \) swept rotor area
- \( J_{WT} \) wind turbine damping coefficient
- \( V_W \) wind speed

**PMSG geometric variables**

- \( R_{rl} \) radius length ratio
- \( r_s \) bore radius
- \( l_c \) machine length
- \( p \) number of pole pairs
- \( g \) air gap
- \( l_m \) magnet thickness
- \( w_m \) magnet width
- \( w_s \) slot width
- \( d_s \) slot depth
- \( w_t \) teeth width
- \( d_y \) yoke thickness
- \( R_{dfr} \) slot depth bore radius ratio
- \( N_{app} \) number of slots per pole per phase
- \( N_{cs} \) number of conductors per slot
- \( K_f \) slot filling coefficient
- \( K_{1b} \) winding factor
- \( V_i \) volume of an element
- \( M_i \) mass of an element
- \( \rho_i \) mass density of an element

**PMSG electromagnetic and electromechanical variables**

- \( \Omega_b \) base speed
- \( T_b \) base torque
- \( P_b \) base power
- \( V_b \) base voltage
- \( \Omega_b \) base speed
- \( \omega_b \) electrical pulsation at the base point
- \( \omega \) electrical pulsation
- \( T_{em} \) electromagnetic torque
- \( i_{b} \) current density
- \( B_y \) yoke induction
- \( B_{1g} \) airgap induction
- \( a_{cm} \) electrical half pole width
- \( K_c \) Carter coefficient
- \( \mu_r \) magnet permeability
- \( B_s \) magnet remanent induction
- \( I_l \) leakage inductance
- \( L_m \) main inductance
- \( L_s \) stator inductance
- \( \Phi_s \) stator flux
- \( R_s \) stator resistance
- \( I_{r} \) stator current
- \( V_s \) stator voltage
- \( P_j \) Joule loss
- \( P_{eddy} \) eddy current loss
- \( P_{hyst} \) hysteresis loss

**PMSG thermal variables**

- \( r_i \) equivalent radius of a component
- \( R_i \) thermal resistance of a component
- \( C_i \) thermal capacity of a component
- \( l_i \) thermal conductivity of a component
- \( T_i \) temperature of a component

**Diode rectifier variables**

- \( R_d \) diode resistance
- \( u_d \) diode voltage drop
- \( I_d \) diode current
- \( P_{cond} \) conduction loss
- \( R_{TH\_RAD} \) radiator thermal resistance
- \( M_{rad} \) radiator mass

---

**Fig. 1.** The "full passive" structure of the wind turbine system.
The corresponding wind turbine torque $T_{WT}$ can thus be expressed:

$$T_{WT} = aU^2 + bU + c$$  \hspace{1cm} (4)

where

$$\begin{align*}
a &= \frac{1}{2\pi}A \times 0.130R^3 \\
b &= \frac{1}{2\pi}A \times 0.117R^2V_W \Omega \\
c &= \frac{1}{2\pi}A \times 0.454RV_W^2
\end{align*}$$  \hspace{1cm} (5)

The dynamic model of the turbine can be represented by:

$$T_{em} = T_{WT} - J_{WT} \frac{d\Omega}{dt} - F_{WT}\Omega$$  \hspace{1cm} (6)

where the wind turbine inertia and the damping coefficient are, respectively, $J_{WT} = 16\ \text{kg m}^2$ and $F_{WT} = 0.06\ \text{N m s/rad}$ is the mechanical shaft speed and $T_{em}$ denotes the electromagnetic torque of the generator.

3. The sizing model of the permanent magnet synchronous generator

The sizing model of the permanent magnet synchronous generator (PMSG) has been developed in [19,21]. It depends on geometrical characteristics (number of pole pairs $p$, number of slots per pole per phase $N_{sp}$, radius/length ratio $R_{rl}$) as well as electromechanical features (current density $J_s$, yoke induction $B_y$, base speed $\Omega_b$ and corresponding power at the base point $P_b$).

3.1. The PMSG geometric model

3.1.1. Calculation of geometrical characteristics

The geometrical characteristics of the generator are shown in Fig. 3.

The bore radius $r_s$ is related to the fundamental value of the air gap magnetic flux density ($B_{1g}$) and the slot depth/bore radius ratio $R_{dr}$ ($R_{dr} = d_s/r_s$) as follows:

$$r_s = \left(\frac{J_bR_{rl}}{K_rB_{1g}R_{dr}p}\right)^{\frac{1}{2}}$$  \hspace{1cm} (7)

where $K_r$ is the slot filling coefficient. $B_{1g}$ is computed from the magnet properties (relative permeability $\mu_r = 1.05$ and remanent induction $B_r = 1.1\ \text{T}$ for NdFeB magnet) and from the electrical half pole width $\alpha_m$:

$$B_{1g} = \frac{4B_r}{\pi} \left(\frac{l_m/g'}{\mu_r + (l_m/g')^3}\right) \sin(\alpha_m)$$  \hspace{1cm} (8)

where $l_m/g'$ represents the ratio between the magnet thickness and the air gap corrected by the carter coefficient. In these two equations, the unknown variables are set to typical values, i.e. $R_{dr} = 0.25$, $K_r = 0.5$, $\alpha_m = 1.31$ (i.e. 75°) and $l_m/g' = 3.5$ while the Carter coefficient is set to 1.05.

The magnet width $w_m$ can be deduced from:

$$w_m = \frac{r_s\alpha_m}{p}$$  \hspace{1cm} (9)

The generator air gap $g$ is calculated from the empirical relation:

$$g = 0.001 + 0.003r_s/\sqrt{R_{rl}}$$  \hspace{1cm} (10)

---

Fig. 2. The Savonius wind turbine with its corresponding power coefficient.

Fig. 3. The geometrical characteristics of the PMSG.
Tooth and slot volumes are then obtained from the bore radius and the number of slots per pole per phase $N_{sp}$:

$$w_s = w_t = \frac{\pi r_b}{6pN_{sp}}$$  \hspace{1cm} (11)

and the slot depth $d_s$ is given by:

$$d_s = R_{st} f_s$$  \hspace{1cm} (12)

Finally, the yoke thickness is obtained as follows:

$$d_y = \frac{r_s}{p} \frac{B_y}{\mu_r + B_y}$$  \hspace{1cm} (13)

where the maximum magnetic flux density in the air gap is evaluated from the following relation:

$$B_y = B_r \frac{I_m}{\mu_r + B_r}$$  \hspace{1cm} (14)

### 3.1.2. Calculation of generator volumes and masses

The generator masses are obtained from the volume of each constitutive element and from the corresponding mass density. The rotor volume $V_{rotor}$ can be approximated as:

$$V_{rotor} = \pi l_{rotor} \left( r_{rotor}^2 - (r_{rotor} - d_y)^2 \right)$$  \hspace{1cm} (15)

where $r_{rotor} = r_s - g - l_m$ and $d_k = d_y$. The corresponding mass is given by:

$$M_{rotor} = V_{rotor} \rho_{iron}$$  \hspace{1cm} (16)

The stator volume $V_{stator}$ is composed of yoke and teeth volumes

$$V_{stator} = V_{teeth} + V_{yoke}$$  \hspace{1cm} (17)

which can be approximated as follows:

$$\begin{cases} V_{yoke} = 2\pi l_d d_y (r_s + d_s + d_y/2) \\ V_{teeth} = \pi l_d d_s (r_s + d_s/2) \end{cases}$$  \hspace{1cm} (18)

The corresponding mass is

$$M_{stator} = V_{stator} \rho_{iron}$$  \hspace{1cm} (19)

The total iron mass in the generator can be expressed by summing stator and rotor iron masses

$$M_{iron} = M_{stator} + M_{rotor}$$  \hspace{1cm} (20)

Similarly, the magnet volume is given by:

$$V_{magnet} = 2\alpha_m l_t \left( (r_s - g)^2 - r_{rotor}^2 \right)$$  \hspace{1cm} (21)

and the corresponding mass by:

$$M_{magnet} = \rho_{magnet} V_{magnet}$$  \hspace{1cm} (22)

with $\rho_{magnet} = 7400$ kg m$^{-3}$.

Finally, the copper mass is deduced from the copper volumes in the slots and in the winding heads

$$\begin{cases} V_{copper} = \pi l_d d_s (r_s + d_s/2) \\ V_{head} = 6\pi l_d d_s (r_s + d_s/2) d_y \omega K_i N_{sp} \end{cases}$$  \hspace{1cm} (23)

which implies

$$M_{copper} = \rho_{copper} \left( V_{head} + V_{copper} \right)$$  \hspace{1cm} (24)

The total mass of the generator is then approximated by summing the masses related to each component:

$$M_{motor} = M_{iron} + M_{copper} + M_{magnet}$$  \hspace{1cm} (25)

### 3.2. The PMSG electric model

#### 3.2.1. Calculation of the electromagnetic parameters

Electromagnetic parameters of the generator are computed from the previous geometric variables. In particular, leakage inductances $L_i$ are obtained from [22] by considering a trapezoidal slot as shown in Fig. 3

$$L_i = 2\mu_0 l_p N_{sp} \lambda_s N_{cs}^2$$  \hspace{1cm} (26)

where $N_{cs}$ denotes the number of conductors per slot and where the $\lambda_s$ coefficient depends on the slot geometrical characteristics (27) and (28).

$$\lambda_s = \frac{2h_1}{3(b_1 + b_3)} + \frac{2h_2}{b_2 + b_3} + \frac{h_3}{b_2}$$  \hspace{1cm} (27)

with

$$\begin{cases} h_1 = 8d_2 K_b/7 \\ h_2 = w_s/8 \\ h_3 = 0.02r_s \\ b_1 = w_s \\ b_2 = w_s/2 \\ b_3 = 3w_s/4 \end{cases}$$  \hspace{1cm} (28)

The main inductance $L_m$ can be expressed as:

$$L_m = \frac{4\mu_0 r_b I_0}{\pi (K_{gb} + \frac{l_m}{\mu_1})} N_{sp}^2 K_{ib}^2 N_{cs}^2$$  \hspace{1cm} (29)

where the winding factor $K_{ib}$ is given by the following relation:

$$K_{ib} = \frac{\sin(\pi/6)}{N_{sp} \sin(\pi/6N_{sp})}$$  \hspace{1cm} (30)

The corresponding stator inductance $L_s$ is defined as follows:

$$L_s = \frac{3}{2} L_m + L_1$$  \hspace{1cm} (31)

It can be noted that these inductance values can also be computed from the generator geometric features with the Finite Element Method [17,18] for a better accuracy.

The magnetic flux $\Phi_s$ and the stator resistance $R_s$ are defined as follows:

$$\Phi_s = 2K_{ib} N_{sp} B_s g f_s l_1 N_{cs}$$  \hspace{1cm} (32)

$$R_s = 12\rho_{copper} \left[ l_1 + \frac{\pi (r_s + 0.5d_s)}{p} \right] \frac{p^2 N_{sp}^2}{\pi r_s d_s K_i}$$  \hspace{1cm} (33)

Finally, the generator current $I_1$ can be obtained from the current density $j_s$:

$$I_s = \frac{j_s d_s K_i \pi r_s}{6p N_{sp} N_{cs}}$$  \hspace{1cm} (34)

To compute all parameters of the generator, the number of conductors $N_{cs}$ in one slot has to be determined. It should be designed in order to fulfill the operating conditions at the base point. The permanent magnet machine must be able to provide the base torque $T_m = T_b$ under the supply voltage $V_m = V_b$ at the electrical pulsation $\omega = \omega_b$. By setting $N_{cs} = 1$ in Eqs. (26), (29), (32), (33)
and (34) circuit variables $l_{11}, l_{m1}, l_{s1}, \Phi_{s1}, R_{s1}$ and $I_{s1}$ can be obtained for one conductor per slot:

\[
\begin{align*}
L_{1} &= N_{c1}^{2} L_{11} \\
L_{m} &= N_{c1}^{2} L_{m1} \\
L_{s} &= N_{c1}^{2} L_{s1} \\
\Phi_{s} &= N_{c1} \Phi_{s1} \\
R_{s} &= N_{c1}^{2} R_{s1} \\
I_{s} &= l_{s1}/N_{c1}
\end{align*}
\]

By considering the electrical diagram of the generator (see Fig. 4), operating at the base point ($T_{b}, \omega_{b}$), the number of conductors in one slot can be obtained by solving (36):

\[
N_{c1}^{2} - \frac{2 V_{b} R_{s1} l_{s1}}{(\Phi_{s1} \omega_{b})^{2} - [R_{s1}^{2} + (l_{s1} \omega_{b})^{2}] I_{s1}^{2}} N_{c1} - \frac{V_{b}^{2}}{2 (\Phi_{s1} \omega_{b})^{2} - [R_{s1}^{2} + (l_{s1} \omega_{b})^{2}] I_{s1}^{2}} = 0
\]

Thanks to the calculation of the circuit parameters ($R_{s}, L_{s}, \Phi_{s}$), a circuit (a,b,c) 3-phase model can be derived. This latter model will be considered as the “reference model” of the generator.

3.2.2. Calculation of the generator losses

Iron losses in the generator are divided into hysteresis ($P_{\text{Hyst}}$) and eddy current losses ($P_{\text{Eddy}}$) in the stator parts (i.e. yoke and teeth). Iron losses in the yoke are computed as follows [23]:

\[
\begin{align*}
P_{\text{Hyst}} &= V_{\text{yoke}} \frac{2 K_{H} \Phi_{y}^{2} \omega}{\pi} \\
P_{\text{Eddy}} &= V_{\text{yoke}} \frac{4 \Phi_{y}^{2} \omega}{\pi^{2} K_{E} B_{y}^{2}}
\end{align*}
\]

where the filling coefficient $K_{E}$ equals 0.833 and $K_{H}$ and $\alpha_{p}$ are empirical factors depending on the material (typically $K_{H} = 52$ and $\alpha_{p} = 0.06$ for FeSi 3%). Similarly, iron losses in the teeth can be deduced by the following relation:

\[
\begin{align*}
P_{\text{Hyst}} &= V_{\text{teeth}} \frac{2 K_{H} B_{\text{teeth}}^{2} \omega}{12 \alpha_{p} N_{c1} \pi} \\
P_{\text{Eddy}} &= V_{\text{teeth}} \frac{12 \alpha_{p} N_{c1} B_{\text{teeth}}^{2} \omega}{\pi^{2}}
\end{align*}
\]

with

\[
B_{\text{teeth}} = \frac{\hat{B}}{0.5 + (d_{5}/3r_{s})}
\]

Global iron losses in the generator are then obtained by summing all hysteresis and eddy current losses:

\[
P_{\text{Iron}} = P_{\text{Hyst}} + P_{\text{Eddy}} + P_{\text{teeth}} + P_{\text{yoke}}
\]

Finally, Joule losses $P_{j}$ can be classically computed as follows:

\[
P_{j} = 3R_{s} I_{s}^{2}
\]

3.3. The PMSG thermal model

An additional circuit model simulates the thermal behavior of all generator constitutive elements (slot copper, slot insulation, stator yoke) with respect to their thermal characteristics (thermal resistance and capacity of the corresponding elements) and regarding external conditions (i.e. the surrounding temperature). This model is coupled with electromagnetic phenomena through iron and Joule losses (see Fig. 5). The expressions of thermal resistances and capacities are not given in the paper but can be found in [18,19].

4. The sizing model of the diode rectifier

A 36MT120 is considered for the diode rectifier. Power losses in the diode rectifier result from conduction losses that can be expressed as:

\[
P_{\text{cond}} = 2 \left( u_{d} i_{d} + R_{d} i_{d}^{2} \right)
\]

where $u_{d}$ is the diode voltage drop and $R_{d}$ represents the diode internal resistance (typically $R_{d} = 3.4$ mΩ and $u_{d} = 0.8$ V). It should be noted that switching losses are neglected. A thermal model of the rectifier based on a classical state-circuit representation allows us to size the thermal resistance of the radiator $R_{\text{THRAD}}$ in order to operate at nominal conditions (i.e. at the generator base point) below the semiconductor temperature limit (typically $T_{\text{max}} = 125$ °C or 398 K). This model is represented in Fig. 6.

By considering that thermal circuit at steady state, the value of the radiator thermal resistance can be deduced as:

\[
R_{\text{THRAD}} = \frac{\Delta T}{P_{\text{cond}} - (R_{\text{TH1}} + R_{\text{TH2}})}
\]
where $\Delta T = T_{\text{amb}} - T_{\text{ambient}}$ (typically $T_{\text{ambient}} = 25^\circ \text{C}$, i.e. 298 K) and $R_{\text{TH1}} = 1.35 \text{ K W}^{-1}$ and $R_{\text{TH2}} = 0.2 \text{ K W}^{-1}$ for the 36MT120 diode rectifier. Then, the radiator length is obtained from the thermal resistance by interpolating manufacturer’s data. We consider three different extrusion profiles of the manufacturer AAVID THERMALLOY for a thermal resistance variation in the range: $0.5 \text{ K W}^{-1} \leq R_{\text{TH,RAD}} \leq 12 \text{ K W}^{-1}$.

Finally, the rectifier mass is approximated by the radiator mass $M_{\text{rad}}$ evaluated from the corresponding length and the mass density per unit length.

5. Model simplification of the passive wind turbine system

5.1. The reference model

A “reference model” has firstly been proposed in order to validate the temporal system simulation [18]. This model associates a complete (a,b,c) circuit model of the generator with a diode bridge rectifier including ideal switches but taking into account the diode overlapping during switching intervals. Since the computational cost associated with the reference model is really too high important in the framework of system optimization, surrogate models have been developed in order to reduce computational times.

5.2. The equivalent DC model

A first simplified causal model has been developed where the synchronous generator with the diode bridge association is replaced with an energetically equivalent DC model valid in average value [17,18]. The synoptic of this model is given in Fig. 7. The causality is symbolized by arrows specifying which physical variables (energetic efforts or flows) are applied to each part of the system. The correspondence between AC (rms) values and DC ones, in the synchronous generator circuit model (see Fig. 8) is given in Table 1.

![Fig. 6. The thermal model of the diode rectifier.](image)

5.4. Validation and comparison of the wind turbine models

To compare and validate the wind turbine models, we consider a “reference generator” similar to that used in our lab in earlier studies [15]. The design variables associated with this generator have been obtained from its electrical and geometrical features by inverting the sizing model of Section 3 (see Table 2).

The electromechanical behavior of the passive wind turbine system is evaluated with the different models considering the reference generator and the typical wind cycle [17], approximated by the following empiric relation:

\[
V_W(t) = 10 + 0.2 \sin(0.105t) + 2 \sin(0.367t) + \sin(1.293t) + 0.2 \sin(3.665t)
\]

In particular the electromagnetic torque and the rotational speed of the generator, simulated with each model on this typical wind cycle, are displayed in Figs. 10 and 11. Although instantaneous values differ, it can be noted that differences are not significant and that average values are close for all models.

In Table 3 we also indicate the average values of the powers in each part of the system during the wind cycle (see Fig. 12). Iron and Joule losses in the PMSG are calculated from Eqs. (40) and (41). Conduction losses in the diode rectifier are computed according to Eq. (43). Mechanical losses in the turbine \( P_{\text{mech}} \) are expressed as follows:

\[
P_{\text{mech}} = P_{\text{WT}} \Omega^2
\]

It can be seen from Table 3 that the energetic behavior (i.e. powers and losses) of the wind turbine system is similar for all models. Note also that the system efficiency is not good without any MPPT control system, which justifies the passive wind turbine generator optimization.
Table 3

Table 4 summarizes the step size used for all models in the ODEs and the corresponding CPU time required for simulating the wind cycle (i.e. 2 min of wind) on a standard PC computer. The CPU time of the most accurate model (i.e. the reference model) is really too high to simulate wind cycles with high durations or in an optimization context where the wind cycle has to be simulated many times. The best CPU time, obtained with the mixed-reduced model, is about 7000 times lower than that of the reference model! With an equivalent accuracy, this demonstrates the interest of the model simplification approach developed in the previous section.

6. Multiobjective optimization of the passive wind turbine

In this section, the optimization of the passive wind turbine system is carried out using a multiobjective genetic algorithm.

6.1. Design variables, constraints and objectives

The design variables considered for the wind turbine optimization and their associated bounds are shown in Table 5. Six variables are continuous (i.e. $R_k$, $P_b$, $V_{pp}$, $B_p$, and $J_s$) and two are discrete (i.e. $p$ and $N_{spp}$). Two conflicting objectives have to be improved with respect to these variables: the useful power has to be maximized while minimizing the total embedded mass of the system.

When varying the design variables in their corresponding range, five constraints have to be fulfilled to ensure the system feasibility. The first two constraints ($g_1$ and $g_2$) concern the number $N_{cs}$ of copper windings per slot. This number has to be higher than one and bounded by the slot section in relation to the minimum winding section $S_{winding}$ (this last is set to 0.5 mm²).

$$g_1 = 1 - N_{cs} \leq 0$$  \hspace{1cm} (52)

$$g_2 = S_{winding} - \frac{d_5 w_5 k_r}{N_{cs}} \leq 0$$  \hspace{1cm} (53)

The third constraint ($g_3$) prevents magnet demagnetization:

$$g_3 = \hat{B}_S - B_D \leq 0$$  \hspace{1cm} (54)

where the magnet demagnetization induction limit $B_D$ is –0.2 T and the stator induction is defined as follows:

$$\hat{B}_S = \frac{3 \mu_0 N_{spp} N_{cs} I_s}{K_g + I_m / \mu_t}$$  \hspace{1cm} (55)

An additional constraint ($g_4$) verifies that the temperature of the copper windings ($T_{copper}$) does not exceed the critical limit of insulators (typically $T_{copper_{max}} = 160 \degree C$ or 433 K) during a wind cycle:

$$g_4 = T_{copper} - T_{copper_{max}} \leq 0$$  \hspace{1cm} (56)

where $T_{copper}$ is evaluated according to the thermal model described in Section 3.3.

Finally, the last constraint ($g_5$) ensures that the temperature on the semiconductor junctions in the diode rectifier stays below the technological limit (typically $T_{j_{max}} = 125 \degree C$, i.e. 398 K) during a wind cycle:

$$g_5 = T_j - T_{j_{max}} \leq 0$$  \hspace{1cm} (57)

where the temperature on the semiconductor junction is calculated according to the thermal model of Fig. 6, from the conduction losses during the wind cycle.

It can be noted that the first two constraints are evaluated before simulating the wind cycle. If one of these constraints is not fulfilled, the next constraints take the maximum penalty value (i.e. $g_{3,4,5} \rightarrow \infty$ “death penalty”). On the other hand, if the first two constraints are fulfilled, the wind turbine system is simulated and the next constraints are evaluated during the wind cycle. Thus, three “cumulative” constraints $G_{1,2,3}$ associated with $g_{1,2,3}$ are defined as follows:

$$G_{1,2,3} = \sum_k \max(0, g_{3,4,5}(k))$$  \hspace{1cm} (58)

where $k$ denotes the set of points defining the wind cycle.

6.2. The optimization process

The non-dominated sorting genetic algorithm (NSGA-II) [24] is used for the optimization of the “full passive” wind turbine generator. The NSGA-II is coupled with the sizing and simulating models presented in the previous sections. The most accurate model, which can be used in an optimization process where multiple simulations are performed, is employed for simulating the wind cycle.
wind turbine behavior. We choose the equivalent DC model since its CPU time is still acceptable for a large number of simulations. For each candidate solution investigated by the multiobjective genetic algorithm, objectives and constraints are evaluated considering the wind cycle defined in Section 5.4.

Note that other wind cycles synthesized from wind statistics have also been used for this optimisation process as presented in [26].

To take into account the design constraints in the NSGA-II, the Pareto-dominance rule is modified as follows:

- if two individuals are non-feasible, the Pareto-dominance relative to these individuals is applied in the constraint space.
- if two individuals are feasible, the Pareto-dominance relative to these individuals is applied in the objective space.
- if one individual is feasible and the other is non-feasible, the feasible individual dominates the non-feasible individual.

In this manner, Pareto ranking tournaments between individuals include the constraint as well as the objective minimization. Note that in the case of the NSGA-II, for non-feasible individuals belonging to a given front in the constraint space, the computation of the $I$-distance density estimator is carried out in relation to all constraints [19]. In this way, niching will occur in the two different spaces (i.e. constraint and objective spaces) and diversity will be preserved to avoid premature convergence.

Fig. 13. Pareto-optimal configurations of the passive wind turbine system.
Five independent runs are performed to take into account the stochastic nature of the NSGA-II. The population size and the number of non-dominated individuals in the archive are set to 100 and the number of generations is $G = 200$. Mutation and recombination operators are similar to those presented in [25]. They are used with a crossover probability of 1, a mutation rate on design variables of 1/m (m is the total number of design variables in the problem) and a mutation probability of 5% for the X-gene parameter used in the self-adaptive recombination scheme.

### 6.3. The optimization results

The best trade-offs determined from the five independent runs are displayed in Fig. 13. The global Pareto-optimal front is obtained by merging all fronts associated with these runs. The characteristics of four typical solutions of the Pareto-front and of the “reference” system (the corresponding design variables of these solutions are mentioned in Table 6) are represented in this figure. It should be noted that the “reference” generator is able to operate at optimal wind powers when it is associated with a MPPT control device but presents a “poor” efficiency if the MPPT is suppressed. As shown in Fig. 13(a), the useful power is strongly reduced in this case. The wind turbine optimization considerably improves both objectives. As can be seen in Fig. 13(c), these passive optimized solutions can match very closely the behavior of active wind turbine systems operating at optimal wind powers by using a MPPT control device. Some Pareto-optimal solutions are slightly better than the initial configuration of the generator with a MPPT control device which still presents the best wind power extraction (see Table 7). However, it can be seen from this table that losses in the system are considerably reduced through the global optimization process, which explains the good efficiency of passive wind turbine configurations.

### 6.4. The model sensitivity analysis

- Comparison with the reference model

To analyse the model sensitivity related to optimization results, we simulate the Pareto-optimal configurations obtained in the previous section with the reference model. In this case, the values of the PMSG inductances used in the reference model are those obtained with the Finite Element Method (FEM) [17]. It can be seen from Fig. 14 that the differences between the most accurate wind turbine model (FEM sizing + reference model simulation) and the equivalent DC model with analytical sizing are rather small.

- Comparison with the mixed-reduced model

The same approach was applied to optimize passive wind turbine configurations using the previous optimization process and the mixed-reduced model (instead of the equivalent DC model). Five NSGA-II runs were performed with the control parameters of Section 6.2. The results obtained with the mixed-reduced and the equivalent DC models were quite identical. Thus, the fastest simulating model (i.e. the Mixed-reduced model) can be used for optimizing passive wind turbine systems in relation to wind cycles with higher durations [26] (more than 200 min of wind) without losing accuracy.

### 7. Conclusions

In this paper, a “low cost full passive structure” of a wind turbine system has been proposed. It has been put forward that an efficient operation of such a device can be obtained only if the design parameters are conveniently and mutually set from a system viewpoint. For that purpose, several sizing and simulating models of the passive wind turbine system have been developed. The simplified model approach leads to a large reduction of computational time which allows the investigation of multiple system configurations through a multiobjective optimization process. In particular, the energetic efficiency has been maximized while the total embedded mass have been minimized, leading to Pareto-optimal configurations.
