A B S T R A C T

This study aims at determining suitable conditions for the preparation of the best organobeidellite starting material used for the development of efficient mesoporous TiO₂ supported beidellite (Bd) photocatalysts. For this purpose, organo-modifications of natural Bd from Agadir Basin (Morocco) were achieved. The influence of (i) the length of alkyl chains C_n (n = 8, 12, 14 and 16) of n-alkyl ammonium surfactants CH₃(CH₂)_{n-1}NH₃⁺ and (ii) the amount of C₁₆ surfactant ranging from 1 to 5 times the smectite (Sm) cation exchange capacity (CEC) on the structure of organo- Bd was studied. XRD, TEM, TG-DTA and FTIR results are consistent with the intercalation of cationic surfactants species in Bd interlayer spaces according to different conformations yielding to their expansion. The interlayer expansion magnitude increased both with the length of alkyl chain and the amount of C₁₆ surfactant. Organomodification with increasing surfactant load beyond 1CEC besides yielded to the adsorption of increasing excess on external surfaces of Bd particles. These controlled structural modifications will be used further in the functionalization of this Bd by TiO₂ nanoparticles to produce efficient supported TiO₂-Bd photocatalysts.

1. Introduction

Clay minerals, especially those of the smectite (Sm) family, are involved in a wide array of applications owing to, besides their natural abundance and low costs, their specific properties such as high cation exchange capacity (CEC), swelling ability, high surface areas and subsequently strong adsorption capacities (Velde, 1995; Bergaya and Lagaly, 2006). Nevertheless, their uses remain limited due to their hydrophilicity related to the presence of hydrated interfoliaceous inorganic cations within their structure that stems from ionic substitutions in their tetrahedral and/or octahedral sheets (Velde, 1995; Bergaya and Lagaly, 2006). They can be rendered hydrophobic by several routes amongst which the exchange of interlayer inorganic cations with organic ones, currently alkylammoniums, which furthermore result in the expansion of their interlamellar spaces (Lagaly, 1986; Lagaly and Dékany, 2005).

These features permit to develop a new class of derivative materials, namely organoclays, which have new versatile innovative applications as adsorbents of organic pollutants (de Paiva et al., 2008; Liu et al.,

2008; Park et al., 2011), rheological control agents (Manias et al., 1996), refractory varnish (de Paiva et al., 2008), thixotropic agent in coating and thickener in ink (Beall, 2003), component in the development of clay polymer nanocomposites (CPN) (Alexandre and Dubois, 2000; Ray and Okamoto, 2003), template in the preparation of graphite film (Isayama et al., 1996) or of mesoporous inorganic heterostructures (Letaïef et al., 2006). In these applications, the behavior and properties of the organoclays are strongly related to the structure and the molecular environment of the intercalated cationic organic species within the silicates interlayer spaces. In this respect, depending on the amount and the kind of the surfactant (mono-, di- or tri-alkyl, chain length...) and on the nature of clay mineral (chemical composition of the sheets, layer charge and its distribution...), cationic surfactant entities could be packed inside interlamellar spaces in the form of lateral mono-, bi- or pseudo tri-layer, or even of paraffin mono- or bi-layer (Lagaly, 1986; Lagaly and Dékany, 2005; Bouna et al., 2011 and 2013).

In the case of CPN, it was reported that the synthesis of the material exhibiting the best properties required organoclay precursor with the largest basal spacing (Vaia et al., 1994; Lagaly et al., 2006). As far as inorganic heterostructured materials are concerned, several works reported the immobilization of SiO₂ nanoparticles on montmorillonite (Mt) (Letaïef et al., 2006) or of TiO₂ nanoparticles on Mt (An et al.,

* Corresponding author.

E-mail address: b.rhouta@uca.ma (B. Rhouta).

2008), sepiolite (Aranda et al., 2008; Gómez-Avilés et al., 2013; Ruiz-Hitzky and Aranda, 2014), palygorskite (Bouna et al., 2011 and 2013) as supported photocatalysts starting from the corresponding organoclays. In such syntheses, the linear alkyl ammonium surfactant (cetyltrimethylammonium ion, namely C_{16}) amount used was equivalent to 3 times the cation exchange capacity (CEC) of the clay mineral. It was suggested that the surfactant acts as a template affording organophilic environment favorable to hydrolysis and condensation of organometallic reagents of Ti or Si (Letaïef et al., 2006; Aranda et al., 2008) and it could be quite completely removed once TiO_2 or SiO_2 nanoparticles respectively are formed without disturbing photocatalytic activity (Aranda et al., 2008; Bouna et al., 2011). It is worth mentioning that no systematic studies were reported on the effects of alkyl chain length or surfactant load both on the microstructure of immobilized oxide (average size and distribution of oxide nanoparticles) onto clay mineral particles and on the photoactivity of the TiO_2 -clay supported photocatalysts.

Organoclays involved in beforehand mentioned applications were mostly prepared starting from Mt which is a Mg-for-Al octahedrally substituted end member of dioctahedral Sm series (Lee and Kim, 2002). He et al (2006) reported that the reaction between a given surfactant and montmorillonites from different occurrences, therefore exhibiting variable chemical compositions inducing different layer charge, *i.e.* different CEC, yielded structurally different organoclays.

More recently, mineralogical, physico-chemical, textural and structural properties of an abundant Bd -rich clay deposit from Agadir basin (Morocco) were reported (Bouna et al., 2012). Bd is different from Mt in that it is an end member of dioctahedral Al- Sm with an average layer charge of 0.6 to 0.7 pretty completely created by the substitution of Si^{4+} by Al^{3+} in the tetrahedral positions (Nadeau et al., 1985). The Bd -rich clay is considered herein as starting material to prepare convenient organobidellite precursors as first step for the synthesis of efficient TiO_2 -supported Bd photocatalysts. The photocatalytic activity will be further optimized by controlling the microstructural features, *i.e.* size and distribution of TiO_2 nanoparticles onto clay mineral particles.

This paper aims at studying the effects of the length of alkyl chain and load of cationic surfactant on the structure of derivative organobidellite that will be used as precursor for the synthesis of TiO_2 -bidellite supported photocatalysts. It will be extended by a companion paper focusing on microstructural and photocatalytic properties resulting from these controlled structural changes. In addition, such organobidellites could be employed as starting materials for the development of other kinds of oxide/Bd- or polymer/clay- nanocomposites.

2. Experimental

2.1. Starting materials

Organomodified Bd were prepared starting from $< 2 \mu m$ Na^+ -exchanged Bd fine fraction (Na^+ - Bd), isolated according to the procedure described elsewhere (Rhouta et al., 2008; Bouna et al., 2012), from the raw clay (Bd) sampled from the region of western high Atlas basin of Agadir (Morocco). The raw clay and corresponding purified Na^+ -exchanged clay fraction were previously characterized in details (Bouna et al., 2012). The Na^+ -exchanged Bd is composed of 93% of Bd, and 7% of kaolinite (Kaol). Its CEC, BET specific surface area, and total pore volume are respectively around 59.7 mEq/100 g, 82.2 m^2/g and 0.136 cm^3/g . The structural formula of Bd was determined after subtraction of Kaol contribution as $(Si_{7.51}Al_{0.49})(Al_{2.99}Fe_{0.68}Mg_{0.33})(Ca_{0.03}Na_{0.54}Mg_{0.11})O_{20}(OH)_4$. It shows dioctahedral aluminiferous features with a structural negative layer charge per half-unit-cell of about 0.41e created by 60% and 40% of isomorphous substitutions in tetrahedral and octahedral sheets respectively.

Linear alkyl chain ammonium bromide compounds $[CH_3(CH_2)_{n-1}NH_3]^+Br^-$, abbreviated C_nBr , having various alkyl chain lengths ($n =$

8, 12, 14 and 16) were purchased from Aldrich and were used as received without further purification.

2.2. Preparation

In order to study the effect of alkyl chain length of surfactants on their intercalation within Bd interlayers, specific samples were prepared. Taking into account molar masses of surfactants, an appropriate amount (equivalent to 3 CEC of Bd considered herein) of these different linear alkyl chain compounds were added to an aqueous dispersion of Na^+ -exchanged Bd (1 wt%). Likewise, to investigate the influence of surfactant loading on its insertion inside Bd interlayer spaces, increasing amounts of cetyltrimethyl ammonium bromide (CTAB) ($C_{16}H_{33}NH_3Br$), equivalent to 1, 3 and 5 CEC of the Sm, were added at the ambient temperature to 1 wt% aqueous dispersion of Na^+ - Bd. After 48 h of stirring, these dispersions were centrifuged to recover corresponding solids which were thereafter washed several times with distilled water to remove surfactant excess as evidenced by the absence of foam and finally dried in an oven at 60 °C for 2 days. The different organomodified Bd samples as synthesized were designated according to the chain length (n) and amount of surfactant (x) expressed in term of the clay mineral CEC as follows: $x C_n^-$ - Bd, where $x = 1, 3$ and 5 and $n = 8, 12, 14$ and 16 atoms of carbon.

2.3. Characterizations

The expansion degree of Bd layers upon organomodification was evaluated by XRD analyses in small angle range ($1 \leq 2\theta \leq 10^\circ$) where the 001 basal reflection is expected and also examining corresponding thin foils by transmission electron microscopy. XRD patterns were recorded using a Seifert XRD 3000TT apparatus ($Cu K_{\alpha 1 + \alpha 2}$ radiation, equipped with a diffracted beam graphite monochromator in the Bragg-Brentano configuration. Microstructural observations were performed with a Jeol JEM 2010 transmission electron microscope (TEM) equipped with an energy dispersive X-ray Tracor analyzer (EDS). A small amount of material powder was first dispersed in ethanol with an ultrasonic bath. After that, droplets of this dispersion were placed on a copper grid (3 mm in diameter) covered by a thin layer of amorphous carbon. After evaporation of ethanol, particles of the sample were retained on the grid which was introduced in the TEM apparatus using a sample holder.

The presence of functional groups characterizing surfactants in organomodified Bd was checked out by Fourier Transformed infrared (FTIR) spectroscopy. Spectra were recorded using a Nicolet 5700 spectrometer under ambient conditions in the frequency range 400-4000 cm^{-1} using KBr pellets. The pellets contained a mixture of 2 mg of clay material with 198 mg of KBr (~1 wt%).

The amount of surfactant retained by Bd upon organomodification was assessed by thermal analysis. The thermogravimetric (TG) and Differential Thermal Analysis (DTA) thermograms were collected using a Setaram Labsys apparatus on sample masses of about 60 mg and using a temperature ramp of 10 °C/min from the ambient to 1000 °C.

The chemical compositions CHN of starting Na^+ -Bd as well as derivative organobidellites (3CTA⁺-Bd and 5CTA⁺-Bd) were determined by using Perkin Elmer 2400 Series II apparatus.

3. Results and discussion

3.1. Effect of the length of alkyl chain

Fig. 1 represents XRD patterns of starting Na^+ -exchanged Bd (Na^+ -Bd) and its modification with an amount equivalent to 3 CEC of surfactants differing in their alkyl chain lengths (n). It shows the shift of the characteristic 001 basal reflection of the Bd towards low angles upon organomodification, *i.e.* towards larger d_{001} values. The shift is increasing with n . Indeed, the basal distance d_{001} , initially at 1.25 nm in

Fig. 1. XRD diagrams of Na⁺-exchanged Bd before and after organomodification with surfactants differing in the length of alkyl chains.

unmodified Bd, is found at 1.40, 1.85, 2.05 and 2.10 nm upon the organomodification with alkylammoniums composed of 8, 12, 14 and 16 carbons, respectively. These results clearly indicate the expansion of Bd interlayer spaces caused by the intercalation of alkylammonium species in these spaces to replace charges compensating Na⁺ interlayer ions. Nevertheless, the difference of expansion degree, observed according to the alkyl chain length of surfactant, denotes that different conformations were adopted by alkylammonium species within Bd interlayer spaces. These conformations depend on alkylammonium entities packing density, which in turn rely on the surface charge density of clay mineral and the surfactant alkyl chain. In fact, as it was reported in the literature (Lagaly, 1986; Lee and Kim, 2002; Lagaly and Dékány, 2005; de Paiva et al., 2008; Liu et al., 2008; He et al., 2010; Wang et al., 2011), the increase of basal distances from 1.25 to 1.4 and 1.85 nm, upon the clay mineral modification with C₈ and C₁₂ surfactants, respectively, are consistent with the arrangement of entities of these surfactants inside Bd interlayer spaces in the form of a monolayer and a bilayer, respectively. On the other hand, the intercalation of C₁₄ and C₁₆ surfactants resulted in quite the same expansion of Bd layers to approximately 2.1 nm. This degree of expansion denotes that both the surfactants might be laid inside Bd interlayer spaces as pseudo trimolecular layer or monolayer of paraffin (Lagaly, 1986; Lagaly and Dékány, 2005; de Paiva et al., 2008; Hu et al., 2013). Nevertheless, it was reported that ammonium groups are best accommodated to oxygen atoms of clay mineral

basal surfaces when they are involved in paraffin monolayer than in pseudo trimolecular layer (de Paiva et al., 2008). In this respect, an expansion magnitude Δd of 1.13 nm was assessed by subtracting the

layer thickness of Sm (≈ 0.97 nm) (He et al., 2006) from the basal distance 2.1 nm beforehand mentioned. Knowing that the alkyl chain length (l) of C₁₆ surfactant molecule (CTAB) is 2.53 nm (He et al., 2006), it can be deduced from the Eq. (1) (Lagaly, 1986; Lagaly and Dékány, 2005; He et al., 2006) that entities of this surfactant are tilted within interlayer spaces of an inclination angle (α) of almost 27° with respect to Bd basal surfaces:

$$\alpha = \sin^{-1}(\Delta d/l) \quad (1)$$

Table 1 gathers basal distances assessed from XRD analysis for a series of organobeidellites versus chain length (n) of the surfactants used, corresponding caused expansion magnitudes and the arrangement mode of their species between Bd layers.

3.2. Effect of C₁₆ surfactant amount

Owing to the high expansion generated by the C₁₆ surfactant, the study was carried out by examining the effect of the load of this surfactant on the structure of organobeidellite derivatives.

XRD diffractograms of Bd modified with different amounts of C₁₆ surfactant expressed as a multiple of CEC reveals that the initial 001 basal reflection of Bd at 1.25 nm ($2\theta = 7.2^\circ$) is shifted to smaller angles

Fig. 3. TEM micrograph showing different basal distances of Bd organomodified with an amount of the CTAB surfactant equivalent to 5 CEC.

Fig. 4. Infrared spectra of $\text{Na}^+\text{-Bd}$ before and after organomodification with different amounts of the CTAB surfactant.

and thus to higher basal spacing d_{001} as the amount of the surfactant increased (Fig. 2). Indeed, upon the modification with an amount equivalent to 1 CEC, the d_{001} distance increased from 1.25 to 1.73 nm ($2\theta = 5.1^\circ$). Likewise, the modification with amounts equivalent to 2 and 3 CEC yields to a same increase of the basal distance to about 2.1 nm ($2\theta = 4.3^\circ$). By contrast, the Bd organomodified with an amount equivalent to 5 CEC exhibits the 001 basal reflection at 3.9 nm ($2\theta = 2.2^\circ$) along with harmonics (002) at 1.95 nm ($2\theta = 4.6^\circ$) and (003) at 1.27 nm ($2\theta = 6.95^\circ$).

These results prove the success of intercalation of the surfactant alkylammonium between Bd layers resulting in the expansion of interlayer spaces. Higher is the amount of the surfactant, higher is the expansion degree. It is worth noting that the 001 basal reflection in samples organomodified with concentrations of CTAB equivalent to 1, 2 and 3 CEC appears less resolved, asymmetric, less intense and broader. Owing to the heterogeneous distribution of layer charge characterizing Sm (Lagaly and Dékány, 2005), this could originate from random rearrangement of cationic species of the surfactant inside Bd interlayer spaces yielding to inhomogeneous Bd layers with some different basal spacings. Thus, the distances assessed above may represent an average of irregular distances of spacings. Nevertheless, the sample obtained upon organomodification with CTAB concentration equivalent to 5 CEC exhibited 001 reflection relatively thinner, more symmetric and with a better resolution. This indicates an ordered structure of CTA^+

species in Bd interlayer spaces yielding to a better homogeneity of layers in this sample.

Dimensional characteristics regarding the molecular conformation of CTAB were reported in details by He et al (2006). As a free molecule, it is characterized by a fixed length of the “nail” about 2.53 nm, consisting of the “nail-head” (0.43 nm) and “nail-body” (2.1 nm). Nevertheless, the height of the CTA^+ differs according to its orientation. Indeed, when the plane of the zigzag arrangement of the carbon atoms of CTA^+ is perpendicular to the plane of the silicate layer, the height of the “nail-body” is ≈ 0.46 nm and that of the “nail-head” is ≈ 0.51 nm. On the other hand, when the plane of the zigzag arrangement of CTA^+ carbon skeleton is parallel to the plane of the clay mineral layer, the heights of “nail-body” and “nail-head” are 0.41 nm and 0.67 nm, respectively. By taking into account these data, the magnitude order of interlayer expansion caused by 1 CEC of CTAB ($\Delta d \approx 0.76$ nm) is rather likely consistent with the height of the “nail-head” of cationic surfactant species when they are arranged in the form of monolayer lying parallel to the plane of Bd layers. This finding is in contrast to that reported by He et al (2006) for Mt from China. The interlayer expansion resulting from modification with 3 CEC ($\Delta d \approx 1.13$ nm) indicates that surfactant entities form monolayer paraffin structure with a tilt angle of about 27° . Upon organomodification with 5 CEC, Bd interlayer spaces were expanded of about $\Delta d \approx 2.93$ nm indicating that surfactant species likely formed bilayer paraffin structure with tilt angle of about 37° .

Table 1 recapitulated basal distances recorded from XRD analysis upon organomodification of Bd by increasing amount of CTAB, corresponding expansion degree and the disposition mode of its entities within Bd interlayer spaces.

TEM micrograph of the most organomodified Bd sample ($5\text{C}_{16}\text{-Bd}$) is shown in Fig. 3. It exhibits the expansion of Bd interlayer spaces as evidenced by interlayer distances ranging from 3.1 to 3.9 nm which proved surfactant intercalation. It is worth noting that the dispersion of these distances is narrow so that it likely denotes a quite homogeneous intercalation of CTAB surfactant whose species seemed to be well ordered within Bd interlayer spaces in agreement with the above XRD data. FTIR spectroscopy carried out on the different organomodified Bd samples (Fig. 4) shows, besides bands characteristic of Bd (Bouna et al., 2012), that higher is the surfactant amount, more intense are the symmetric and asymmetric stretching vibrations at 2924 and 2853 cm^{-1} , respectively. These spectra also show their corresponding deformation vibrations at 1490 and 1470 cm^{-1} , which are the fingerprint of CTAB surfactant species.

Furthermore, thermal analysis, performed on different organomodified Bd samples based on C_{16} surfactant investigated herein, reveals for temperature ranging from 200 to 750 $^\circ\text{C}$, mass losses on TG thermograms (Fig. 5a) associated to exothermic effects on DTA curves (Fig. 5b), due to the thermal degradation of CTAB surfactant. These organic mass losses increased with the amount of the used organo-modifying

Fig. 5. TG (a) and DTA (b) Thermograms of $\text{Na}^+\text{-Bd}$ before and after organomodification with different amounts of CTAB surfactant.

Table 2

Comparison between experimental organic losses recorded in the temperature range [200–750 °C] upon thermal analysis performed on Na⁺-beidellite organomodified with different amounts of CTAB surfactant and theoretical ones calculated according to the Eq. (2).

	Experimental organic loss (wt %)	Theoretical organic loss (wt %)
1 CEC	14	14.2
3 CEC	28	33.0
5 CEC	37	45.2

agent (Table 2). These experimental losses are quite consistent with those theoretically predicted from Eq. (2) taking into account the x times

CEC used of the Bd (herein, x = 3) and molar mass of the surfactant cation (M_{CTA}^+) (Wang et al., 2011) (Table 2):

$$Q_{CTA^+} = \left[\frac{(x_{CEC} \times M_{CTA^+} \times 10^{-3})}{(x_{CEC} \times M_{CTA^+} \times 10^{-3} + 100)} \right] \times 100\% \quad (2)$$

These results were further supported by CHN analysis. Indeed, findings reported in Table 3 showed that while the mass contents of C, H and N elements were as expected quite negligible in unmodified beidellite (Na⁺-Bd), they however increased in derivative organoclays (3CTA⁺-Bd and 5CTA⁺-Bd) with the increase of CTAB loads used for beidellite organomodification. Taking into account the chemical formula of the CTAB on one hand and the CEC (≈ 60 meq/100 g) of the beidellite on the other hand, the amounts of C, H and N corresponding to the complete exchange of beidellite interlayer Na⁺ ions with CTA⁺ entities can be deduced as equivalent to 10, 2 and 1 wt% respectively. These amounts were lower than those determined by CHN analysis of 3CTA⁺-Bd and 5CTA⁺-Bd. This likely denoted that while a sufficient same part of CTA⁺ was intercalated in beidellite interlayer spaces according to arrangements established above for 3CTA⁺-Bd and 5CTA⁺-Bd organoclays to compensate the totality of permanent layers charges, the excess of CTAB was probably adsorbed outside on external surfaces of Bd particles. It seems that this excess of CTAB is higher in 5CTA⁺-Bd with respect to 3CTA⁺-Bd.

4. Conclusions

This study aimed at examining the behavior of an aluminiferous Bd from Agadir basin, Morocco, toward organomodification with linear alkyl chain ammonium surfactants in the objective to use these organobeidellite precursors for the further preparation of efficient TiO₂ supported Bd photocatalysts. The study of the influence of the length of the alkyl chain of surfactant shows that the best expansion of Bd interlayer spaces is achieved with surfactants whose carbon atoms number is beyond 14. The study of the influence of the amount of CTA⁺ (i.e surfactant composed of 16 C) shows that the concentration of 1 CEC, 3 CEC and 5 CEC leads to an arrangement of CTA⁺ species inside Bd interlayer spaces in the form of monolayer perpendicular to the plane of clay mineral, paraffin monolayer and paraffin bilayer, respectively oriented according to tilt angles of about 27 and 37°, respectively. Not intercalated surfactant excess, which was higher

Table 3

Mass contents of C, H and N elements in unmodified Na⁺-exchanged beidellite (Na⁺-Bd) and its derivative organobeidellites (3CTA⁺-Bd and 5CTA⁺-Bd).

Elements Samples	C (wt%)	H (wt%)	N (wt%)

when using amount equivalent to 5CEC than 3CEC, was adsorbed on external surfaces of Bd particles.

This practical and useful study is continued in a companion paper that reports the influence of these structurally different organobeidellites, i.e. 3CTA⁺-Bd and 5CTA⁺-Bd, on the microstructure of TiO₂ (crystalline phase, particles size and distribution) supported on Bd, and thus on the photocatalytic activity of supported TiO₂-Bd catalyst towards the removal of pollutant from aqueous media.
