Cercopithecoides

Despite the abundance of well-preserved crania and natural endocasts in the South African Plio-Pleistocene cercopithecoid record, which provide direct information relevant to the evolution of their endocranial characteristics, few studies have attempted to characterize patterns of external brain morphology in this highly successful primate Superfamily. The availability of non-destructive penetrating radiation imaging systems, together with recently developed computer-based analytical tools, allow for high resolution virtual imaging and modeling of the endocranial casts and thus disclose new perspectives in comparative paleoneurology. Here, we use X-ray microtomographic-based 3D virtual imaging and quantitative analyses to investigate the endocranial organization of 14 cercopithecoid specimens from the South African sites of Makapansgat, Sterkfontein, Swartkrans, and Taung. We present the first detailed comparative description of the external neuroanatomies that characterize these Plio-Pleistocene primates. Along with reconstruction of endocranial volumes, we combine a semi-automatic technique for extracting the neocortical sulcal pattern together with a landmark-free surface deformation method to investigate topographic differences in morphostructural organization. Besides providing and comparing for the first time endocranial volume estimates of extinct Plio-Pleistocene South African cercopithecoid taxa, we report additional information regarding the variation in the sulcal pattern of Theropithecus oswaldi subspecies, and notably of the central sulcus, and the neuroanatomical condition of the colobine taxon Cercopithecoides williamsi, suggested to be similar for some aspects to the papionin pattern, and discuss potential phylogenetic and taxonomic implications. Further research in virtual paleoneurology, applied to specimens from a wider geographic area, is needed to clarify the polarity, intensity, and timing of cortical surface evolution in cercopithecoid lineages.

1. Introduction

Recent research employing three dimensional (3D) imaging techniques has provided important insights into the brain organization of early cercopithecoids and hence Old World monkeys as a
whole (Gonzales et al., 2015). However, relatively little is known about patterns of cercopithecoid brain evolution more generally, despite the extensive Plio-Pleistocene fossil record. The handbook of previous studies has focused mainly on one genus, Theropithecus (Falk, 1981; Elton et al., 2001), or estimating endocranial volume (ECV; e.g., Martin, 1993), although more recent work has highlighted the potential utility of examining the internal morphostructure of Plio-Pleistocene cercopithecoids (Beaudet, 2015; Beaudet et al., 2015, 2016). In part, the lack of attention has been because of a paucity of natural endocasts plus methodological limitations in studying cranial material, notwithstanding its abundance. Fortunately, recent advances in the use of high-resolution 3D imaging and computer-assisted analytical approaches have provided the means with which to examine, in much more detail, cranial material from the extensive Old World monkey fossil record and hence fill important gaps in our knowledge of cercopithecoid brain evolution.

The Plio-Pleistocene cercopithecid record of South Africa samples at least seven cercopithecoid genera and up to 12 species, with fossil material including several complete skulls and/or nearly intact natural endocasts (Freedman, 1957; Szalay and Delson, 1979; Delson, 1984, 1988; Jablonski, 2002; Gilbert, 2007, 2013; McKee et al., 2011). Three Parapapio species currently recognized in South Africa (Parapapio broomi, Parapapio jonesi, and Parapapio whitei) plus the “Parapapio” morph identified at Taung and originally attributed to Parapapio antiquus (Freedman, 1957; Szalay and Delson, 1979), along with three extinct variants of Papio: Papio angusticeps, Papio izodi, and Papio robinsoni (Freedman, 1957; Delson, 1984; McKee, 1993; McKee and Keyser, 1994). All the Parapapio taxa (including some material attributed to Pp. antiquus) plus P. izodi contain specimens for which endocranial morphology can be assessed. Theropithecus oswaldi is also found in South Africa, divided into three chronospecies (from oldest to youngest): Theropithecus oswaldi darti, Theropithecus oswaldi oswaldi, and Theropithecus oswaldi leakeyi (Leakey, 1993; Frost and Delson, 2002; Frost, 2007). Although Plio-Pleistocene Theropithecus brain evolution has been the subject of previous work (Falk, 1981; Elton et al., 2001), sampling the T. o. darti material from Makapansgat is particularly relevant as it was not included in Falk’s seminal 1981 study of sulcal patterning and its implications for function and evolutionary history. Aspects of endcranial form can also be studied in T. o. oswaldi from Swartkrans, but unfortunately not in two further large-bodied papionin taxa, Dinopithecus ingens and Gorgopithecus major, as they are represented mainly by fragmentary remains (Freedman, 1957; Delson, 1984; Jablonski, 2002; Jablonski and Frost, 2010). The same is true for specimens from Kromdraai, Makapansgat, and Swartkrans that have been assigned to Cercocetus sp. (Eisenhart, 1974; Delson, 1984, 1988). However, it is possible to examine Cercopithecoides williamsi, one of two extinct colobine species (the other being Cercopithecoides haasgati) recognized in the South African Plio-Pleistocene (Delson, 1984, 1988; Jablonski, 2002; McKee et al., 2011), which provides insight into the colobine as well as the cercopithecine radiation. The fossil monkeys from South Africa are therefore an appropriate and suitably diverse group on which new methodological advances can be applied to increase our knowledge of cercopithecoid brain evolution.

Knowledge of primate brain evolution is based both on comparative information from living species whose brains and behavior can be directly investigated (Armstrong and Falk, 1982) and the interpretation of paleoneurological evidence. To date, much of that paleoneurological evidence has come from the study of endocasts. Fossil endocasts consist of replicas of the internal table of the bony cranialbase and provide the only direct evidence of brain evolution. When the neurocranium is filled with sediment during fossilization, morphological information about the external brain surface may be preserved as a natural endocast, as illustrated in the South African primate fossil record (Brain, 1981; Holloway et al., 2004). Endocasts constitute a proxy for investigating and quantifying variations in brain size, global brain shape, and neocortical surface morphology, including imprints of cerebral convolutions (i.e., gyri and sulci; Holloway, 1978; Holloway et al., 2004; Falk, 2014; Neubauer, 2014). Given the intimate relationships and patterns of co-variation between brain growth and development and its neocranial bony container, endocasts are suitable proxies when assessing original brain size and morphological details. Recent comparisons between endocranial organization in the brain and endocranial virtual replicas of primate individuals support the close correspondence between endocranial impressions and cerebral sulci and gyri (e.g., Kobayashi et al., 2014).

Following pioneering research in defining the several levels of evidence that can be collected from endocasts, including gross brain size, delineation of cerebral areas, and major sulcal and gyral identifications (Holloway, 1978), availability of non-destructive penetrating radiation imaging systems, together with recently developed computer-based analytical tools, have allowed for high resolution virtual imaging and modeling of endocast, thus disclosing new perspectives in comparative paleoneurology (Zollikofer et al., 1998; Zollikofer, 2002; Gunz et al., 2009; Weakley and Bookstein, 2011). Digital data make the quantitative analysis of overall endocranial shape possible, notably through geometric morphometric methods (Brunner et al., 2003, 2009, 2010; Brunner, 2004; Neubauer et al., 2009, 2010; Gunz, 2015) and registration of surfaces from the correspondence of anatomical landmarks (Specht et al., 2007). However, the use of a traditional methodological toolkit based on landmarks, semilandmarks, and curves, even if efficient in compartmentalizing the endocranial cavity, captures little information about the brain itself and its subdivisions. One potential compromise thus proposed in this study is to combine a detailed analysis of sulcal pattern via automatic detection of the neocortical surface together with the characterization of overall endocranial shape via deformation based-models (Durrelman et al., 2012a, b; Dumoncel et al., 2014; Beaudet, 2015). We also aim to show that the different types of evidence available from endocasts and described by Holloway (1978) can be accessed and assessed reliably for South African fossil cercopithecoid endocrania by means of advanced methods of high-resolution 3D imaging and computer-assisted analytical approaches.

In this paper, along with furthering the development of methods for visualizing and quantifying sulcal pattern and endocranial shape, we report new estimates of ECV (a reliable estimate of actual brain size; Isler et al., 2008) for eight South African cercopithecoid taxa. We also consider the implications of our data on endocranial morphology for improving knowledge of the South African cercopithecoid fossil record, including the taxonomy and evolutionary history of Plio-Pleistocene monkeys, that may be derived from study of sulcal patterns and global shape. We are particularly interested in examining two main issues: (1) variation in sulcal pattern in Theropithecus, and (2) the endocranial morphology of C. williamsi. Falk (1981) noted distinct features in the sulci of T. o. oswaldi, specifically a ‘hook-like’ configuration of the central sulcus, which was not evident in Theropithecus gelada, and by extending the sample to South African fossils, we explore variation and divergence in the Theropithecus lineage further, which in turn gives clues to the evolutionary history of that highly successful and widespread Plio-Pleistocene radiation. Other work on sulcal patterning (Connolly, 1950; Radinsky, 1974; Falk, 1978) has also highlighted taxon-based gross sulcal patterning, for example discriminating between colobines and cercopithecines. Further examination of possible cercopithecine/colobine distinctions is
especially interesting given the presence of *C. williamsi* in the South African Plio-Pleistocene fossil monkey assemblage: despite a typical colobine dental morphology and pollical reduction indicating membership of the extant African colobine clade (Delson, 1975; Szalay and Delsion, 1979; Frost et al., 2015), the locomotor and dietary behavior of *C. williamsi*, along with its large size, is consistent with a terrestrial lifestyle that differs substantially from the arboreal existence observed in its living counterparts (Birchette, 1981; Leakey, 1982; Codron et al., 2005) and in many ways seems quite papionin-like. Quantifying its endocranial morphology thus helps to build a fuller picture of this fascinating animal.

2. Material and methods

2.1. Sample

Our fossil sample includes 14 specimens from four South African Plio-Pleistocene sites (Makapansgat [Member 4], Sterkfontein [Member 4], Swartkrans [Member 1], and Taung; Brain, 1981; Heaton, 2006), detailed in Table 1.

Our comparative sample of extant specimens (n = 46) comprises 11 cercopithecoid genera with both sub-adult and adult individuals (dental age ranging from M3 crown emergence to complete emergence and root apical closure; Table 1). Given that the M1 emergence occurs near the time of the cessation of neural growth (Smith, 1991) and that the main cerebral developmental processes (i.e., corticogenesis) are observed in utero or early in the post-natal period in cercopithecine primates (Fukunishi et al., 2006; Malkova et al., 2006; Kashima et al., 2008; Sawada et al., 2009), we assume that the endocasts extracted in our sample are directly comparable.

2.2. Scanning protocol and endocast reconstruction

All of the specimens investigated in this study have been detailed by micro-focus X-ray tomography (µCT) using various systems detailed in Table 1, except for one of the *Mandrillus* individuals detailed by cone beam computed tomography (CBCT) with a spatial resolution of 200 µm because of its large dimensions. The isometric voxel size of the reconstructed volumes ranges from 32.7 to 200 µm (Table 1).

The virtual extraction and reconstruction of endocrania were performed through two distinct protocols. In the case of fossil specimens, with the exception of SK 561, the sediments filling the endocranial cavity were digitally separated from the bony remains through semi-automatic threshold-based segmentation via the Avizo v8.0 software (Visualization Sciences Group Inc.). The virtual endocranial volumes were extracted from the representatives of the extant genera and the fossil specimen SK 561 by using the Endex software (Subsol et al., 2010; http://liris.cnrs.fr/gilles.gesquiere/wiki/doku.php?id=endex).

2.3. Taphonomic processes and virtual reconstruction

In our fossil sample, six specimens were affected by taphonomic processes and virtually reconstructed (Supplementary Online Material [SOM] Figs. S1 and S2 and related comments in SOM Material and methods). On the whole, the observed diagenetic damages were classified into three categories. First, in the neurocrania of STS 565, MP 221, MP 222, and MP 224, part of the cranial vault is missing, creating a significant hole in the endocranial surface (SOM Figs. S1 and S2). Based on the morphology of the available bony parts, the non-preserved regions were artificially and automatically closed by digitizing a curve network around the margin of the missing area and by creating a non-uniform rational basis-spline (NURBS) surface that matched the points along the curves through the Rhino v5.0 software (R. McNeel & Associates; Benazzi et al., 2011). The second category concerns the specimen STS 564, which lacks the left hemisphere (SOM Figs. S1 and S2). In order to generate a complete volume, the well preserved right side was mirrored to artificially reconstruct the opposite side (Gunz et al., 2009). Finally, the last category refers to the specimen TP 8, in which a fissure separates the endocranial filling into two distinct parts that were virtually stitched together (SOM Figs. S1 and S2).

2.4. Endocranial volumes

Endocranial volumes (ECV) were assessed in 51 extant and fossil cercopithecoid specimens identified at the species level. Measurements of ECV have been computed from the unsmooth 2D segmentation labels (“Material statistics” module available on Avizo v8.0). For damaged fossils (i.e., STS 564, STS 565, MP 221, MP 222, MP 224), reconstructed surfaces were used in analysis (SOM Figs. S1 and S2). Given the allometric relationship between ECV and body mass in primates (Iler et al., 2008), logged (base 10) ECV values were plotted against logged (base 10) body mass estimates, with body mass estimates derived from Smith and Jungers (1997), Delson et al. (2000), and Scott (2011). We consider our ECV analyses to be exploratory and preliminary since aspects such as phylogenetic regression and allometry will not be discussed here.

2.5. Deformation-based models

To compare endocranial morphology between species, we used a landmark-free method that relies on the calculation of group-average surface models and their deformation onto the investigated surfaces (Durrell et al., 2012a, b; Dumoncel et al., 2014, 2016; Beaudet, 2015). The deformation-based models differ substantially from geometric morphometrics methods because (i) they are not based on prior definition of homologous points but on correspondences between continuous surfaces and (ii) statistics are not performed on the positions of individual points but on deformations (see Durrell et al., 2012a for further details). Examining deformations between surfaces, mathematically modeled as a “diffeomorphism,” is particularly appropriate for comparing overall shapes and local orientation in the field of computational anatomy (Guenès and Joshi, 2006; Durrell et al., 2014).

The overall process includes several successive computational steps, illustrated in Figure 1. As a pre-processing step, the surfaces were rigidly aligned in position, orientation, and scale with respect to a reference surface (randomly selected) using the iterative closest point (ICP) algorithm (Fig. 1A). Second, a shape model, called global mean shape (GMS), is computed from the set of aligned surfaces. The construction is done using an iterative optimization algorithm described in Durrell (2010), which uses an ellipsoid surface as input (Fig. 1B) and yields the GMS as output (Fig. 1C). The algorithm also yields deformation fields, which are the parameters of non-linear deformations registering the GMS to each specimen. They are distributed in a 3D grid enclosing the surfaces and common to all the registration procedures between the GMS and the specimens (see Durrell, 2010 for further technical details; Fig. 1C). In our analyses, because the fossil specimens may be taphonomically deformed, GMS was estimated using the extant specimens only. Additionally, based on the results provided by the third step, a taxon mean shape (TMS) was computed for each extant taxon represented in our sample (Fig. 1D). Finally, the Plio-Pleistocene specimens were included in the analysis and the GMS was deformed to each individual (Fig. 1E).

---

* Unless mentioned, the specimens from Sterkfontein and Swartkrans derive from Member 4 and Member 1, respectively, and those from Makapansgat are from Member 4 (Brain, 1981; Heaton, 2006).

* Abbreviations for storage locations: Ditsong = Ditsong National Museum of Natural History, Pretoria; Wits = University of the Witwatersrand, Johannesburg; MNHN = Muséum national d'Histoire naturelle, Paris; MRAC = Musée royal de l'Afrique centrale, Tervuren; AMNH = American Museum of Natural History, New York; MHNT = Musée d'Histoire naturelle de Toulouse.

* Uncertain stratigraphic localization, but an attribution to Member 4 is proposed by the catalog of the University of the Witwatersrand for M 3133, and the descriptions of MP 221 and MP 224 by Freedman (1976) suggest an origin in Member 4.
Based on the deformation framework, we generated (i) a GMS associated with a set of deformations from the GMS to each endocranium (hereinafter called “GMS-to-individuals”) computed from our extant sample, (ii) a TMS for each extant genus investigated in our study and represented by more than two individuals, and (iii) deformations from the GMS to fossil endocasts. In addition to GMS-to-individuals deformations, the GMS was also deformed to the TMS (hereinafter called “GMS-to-TMS”).

The magnitude of the displacements recorded during the deformation process (i.e., GMS-to-individuals and GMS-to-TMS) were rendered by color maps from dark blue (in the web version) (lowest displacement values) to red (highest displacement values) on the endocast surfaces (i.e., TMS and individual endocasts; Fig. 1F). In combination with the cartographies, the directions and magnitudes of the deformations from the GMS to the TMS/individuals are represented by vectors (Fig. 1F).

2.6. Semi-automatic sulci detection

Some cortical details, including the sulcal imprints, were evident in most of the fossil specimens (SOM Figs. S1 and S2). Sulcal pattern is usually identified and described by visual inspection of the endocranial surface. Based on previous studies (Subsol, 1995, 1998), we here use an automatic method for the identification of neocortical relief in endocasts that includes the algorithm presented by Yoshizawa et al. (2007, 2008) for the detection of topographical variations (i.e., crest lines) in 3D meshes. The sulci are considered to be variation points of the surface on a triangle mesh and detected via a geometry-based method using curvature lines computed on the surface. More precisely, the crest lines are defined as salient subsets of the extrema of the principal curvatures on surfaces. The detected structures were corrected manually by removing the non-anatomical features (e.g., cracks due to taphonomic damage), using “The Primate Brain Bank” (www.primatebrainbank.org) and published studies of cercopithecoid endocasts as references (e.g., Connolly, 1950; Falk, 1978, 1981). This “cleaning” step was performed using a program created with MATLAB R2013a v8.1 (Mathworks) by one of us (J.D.).

2.7. Multivariate analyses

The deformation fields integrating local orientation and the amplitude of the deformations from the GMS to each specimen (i.e., GMS-to-individuals) were statistically analyzed by computing a between-group principal component analysis (bgPCA; Durrleman, 2010; Mitteroecker and Bookstein, 2011). Based on the covariance matrix of the predefined extant group means, the fossil specimens were subsequently projected into the shape space. Shape changes and morphological trends observed in the specimens/clusters plotted were depicted by color maps and vectors. A hierarchical clustering on principal components (HCPC) tree, integrating all the bgPCA components, was generated using the FactoMineR package (Lê et al., 2008) for R v.3.2.1 (R Development Core Team, 2015).

3. Results

3.1. Endocranial volumes

The endocranial volumes measured for both extant and fossil cercopithecoid specimens are presented in Table 2 and plotted against body mass in Figure 2. Of these species, Chlorocebus, Erythrocebus, and Cercopithecus have the smallest ECVs relative to body mass. Taking their “medium” body masses into account, the
mangabeys Cercocebus and Lophocebus have relatively larger endocranial capacities than do the colobines Colobus and Piliocolobus. Most of the living papionins plot on the upper range of the ECV estimates, with Papio having the largest ECV relative to body mass. On the contrary, the Macaca individuals are distributed toward the lower estimates of the papionin cluster. All the fossil specimens fall within or close to the lower limit of extant papionin variation, even C. williamsi, which lies closer to extinct Theropithecus than to extant colobines.

### 3.2. Morphoarchitectural variation

The bgPCA analysis of endocast deformations is shown in Figure 3 and the color maps illustrating the changes from the GMS to each TMS of extant and fossil individuals are depicted in Figures 4 and 5 and SOM Figure S3. On the whole, three main groups are evident based on the distribution of the living specimens in shape space, corresponding to the three cercopithecoid tribes (Cercopithecini, Papionini, and Colobini) represented in our study (Fig. 3, see also comments in the SOM Results). Along the second component bgPC2, the extant representatives of the cercopithecine genera Cercocebus, Chlorocebus, and Erythrocebus are grouped together in the negative values and are clearly separated from the rest of the sample. The extant papionins are grouped in the positive values of both axes. The colobines Colobus and Piliocolobus are found in the positive space of bgPC2 and negative values of bgPC1. The fossil papionins plot between the colobines and Mandrillus/Papio, close to Macaca and the mangabeys (Fig. 3). The fossil specimens attributed to Parapapio and Papio are roughly characterized by an elongation and a relative elevation of the frontal pole compared to the GMS (Fig. 4). The occipital lobes are shifted inferiorly and their volumes are significantly reduced in comparison to the GMS. The endocranial regions affected by taphonomic processes and virtually corrected in STS 565, MP 221, and MP 224 do not contribute to excessive local deformations. The large vector identified in the inferior part of the TP 7 endocast could be related to the manual segmentation performed for the extraction of the

### Figure 2

Log endocranial volume (ECV) against log body mass for Plio-Pleistocene and extant cercopithecoid specimens. For specimens for which sex is not known (i.e., one Chlorocebus aethiops, one Colobus guereza, one Cercocebus atys, one Mandrillus leucophaeus, plus the Cercopithecoides williamsi neurocranium MP 36), both the male (higher) and the female (lower) body masses are plotted and the corresponding symbols linked by dotted lines.

### Figure 3

Between-group principal component analysis (bgPCA) of the deformation-based shape comparisons of the endocasts extracted from Plio-Pleistocene and extant cercopithecoid specimens.
The condition displayed by the taxonomically undetermined specimen STS 538 is close to the Parapapio and Papio specimens, notably by the elevation of the superior surface and the lower position of the occipital lobes.

The T. o. oswaldi specimen SK 561 is relatively close to the extant representatives of this genus in the bgPCA (Fig. 3). These affinities are explained by the elevation of the superior parietal surface and by the reduction of the temporal lobes (Fig. 5 and SOM Fig. S3). However, the vectors oriented inferiorly, strongly marked, suggest potential diagenetic disorders affecting the surface in contact with the basicranium. The two T. o. darti specimens, M 3073 and MP 222, group more closely with fossil Parapapio and Papio and with the Macaca and Lophocebus conditions than with extant Theropithecus in shape space. The color maps point out a significant contraction of the parietal superior surface for MP 222, corresponding to the
reconstructed region and responsible for the relative elevation of the occipital and frontal lobes. The M 3073 specimen is close to the GMS and differs from the reference mainly by a bi-temporal enlargement.

The deformation pattern displayed by the fossil specimen M 3055, attributed to C. williamsi and included in extant colobine variability in the bgPCA, is shared with extant colobines (Fig. 5 and SOM Fig. S3). On the contrary, the two other C. williamsi specimens, MP 36 and MP 3a, are closer to the fossil papionins than to the extant colobines. MP 3a shares temporal lobe reduction with living colobines as illustrated by the vectors oriented ventro-dorsally (Fig. 5 and SOM Fig. S3), although it also has substantial contraction of the left occipital lobe.

The HCPC computed on the results of the deformation process is shown in Figure 6. As for the bgPCA, our sample is roughly divided into three main clusters corresponding to the tribes Papionini, Colobini, and Cercopithecini. Among the Papionini, the extant representatives of Papio (Fig. 6, group G) and Mandrillus (Fig. 6, group F) are clearly separated from the other members of the tribe, in accordance with the specific morphology depicted by the color maps and the vectors (SOM Fig. S3). The affinities of SK 561 with extant Theropithecus are supported by its inclusion among the geladas, and so is the relationship between M 3055 and the extant colobines. As previously mentioned, MP 222 is close to Macaca, but the influence of the reconstructed cranial vault needs to be clarified. Interestingly, the majority of the fossil specimens are included in groups D and E of Figure 6, which separate the specimens of Makapansgat from the specimens of Sterkfontein and Taung, independent of individual taxonomic affiliation. The Makapansgat group also includes the Lophocebus specimens. According to the deformation maps (Figs. 4 and 5 and SOM Fig. S3), the shift of the occipital lobes to an inferior position is combined with an elongation of the frontal pole for the Makapansgat specimens, contributing to a relatively straighter overall profile than the Sterkfontein and Taung specimens, which are more globular.

3.3. Sulcal pattern

The extant cercopithecoid sulcal condition, including members of the cercopithecin, papionin, and colobinan tribes, is represented by selected specimens in SOM Figures S4 and S5 and described in related comments (SOM Results). In summary, the basic cercopithecin sulcal pattern that we observed in this sample corresponds to the previous descriptions of Connolly (1950) and Falk (1978). One of the most critical neocortical features that helps discriminate the colobine brain (both African and Asian) from the cercopithecine cerebral condition is the presence of a paroccipital sulcus (Falk, 1978). Unfortunately, because of relatively faint sulcal imprints in the parietal and occipital regions of endocasts, we were not able to detect this critical structure in our endocasts.

Results of the automatic detection of neocortical sulci in the fossil sample are illustrated in Figures 7 and 8 for Papio, Parapapio, Theropithecus, and Cercopithecoides. Globally, Parapapio and fossil Papio from Makapansgat, Taung, and Sterkfontein exhibit the extant papionin sulcal pattern (Fig. 7 and SOM Fig. S4). The frontal fissures are composed of a V-shape arcuate sulcus and a principal sulcus that diverges from the orbital margin. The subcentral anterior sulcus is potentially identified in STS 564, as well as in MP 221 and MP 3133, and is close to the arcuate sulcus. The presence of the subcentral posterior sulcus is suggested for M 3133 based on its posterior position in relation to the inferior part of the central sulcus. The inferior extremities of the central and the intraparietal sulci are curved caudally and rostrally, respectively, as also seen in extant papionins (Fig. 7 and SOM Fig. S4). The inferior occipital sulcus is found in all fossil Papio and Parapapio specimens with the exception of MP 224 and TP 8. The lateral sulcus systematically

![Figure 6](image-url)
intercepts the superior temporal sulcus except in the left hemisphere of MP 221. Finally, the overall fissure pattern observed in the taxonomically undetermined specimen STS 538 is close to the *Parapapio* condition.

While the principal sulcus position in *T. o. darti* is close to the papionin pattern (Fig. 8), the arcuate sulcus is relatively curved, as in colobines (SOM Fig. S5). The subcentral anterior sulcus is identified on the right hemisphere of M 3073 and is connected to the arcuate sulcus. The subcentral posterior sulcus on the left hemisphere of M 3073 is linked with the central sulcus, whereas the central sulcus curves sharply in a caudal direction in the right hemisphere (‘hook-like’ configuration). The intraparietal and lunate sulci are relatively straight and the inferior occipital sulcus is identified only on the left hemisphere in the case of M 3073.

For *C. williamsi*, except in the left hemisphere of M 3055, the lateral and temporal superior sulci converge but do not intercept, in a similar fashion to *Colobus*. The frontal sulcal pattern in *C. williamsi* specimens MP 3a and MP 36 is similar to that of the extant papionins, based on the presence of relatively straight grooves and

**Figure 7.** Virtual reconstructions of *Parapapio* endocasts with sulcal impressions in superior (sup), lateral (lat) right (r), and left (l) views (arc = sulcus arcuatus, ip = sulcus intraparietals, ls = sulcus lunatus, lc = sulcus calcarinus lateralis, oci = sulcus occipitalis inferior, p = sulcus principalis, s = sulcus lateralis, ts = sulcus temporalis superior, sca = sulcus subcentralis anterior, scp = sulcus subcentralis posterior). Only sulci mentioned in the text are labeled. Question marks indicate uncertain sulcal identifications. Images are not to scale.
the divergence of the principal sulcus from the orbital margin, whereas the configuration in M 3055 is colobine-like (Fig. 8). The position of the subcentral anterior sulcus in the right hemispheres of MP 36 and M 3055 is similar to that described for Colobus (SOM Fig. S5), but also to fossil papionins (Fig. 7). In all three specimens investigated, the inferior end of the central sulcus is curved, as in contemporaneous fossil papionin specimens. The configuration of the central sulcus in MP 36 differs from the two other specimens, having a very short cleft connected inferiorly, which could potentially be identified as the sulcus subcentralis posterior, contributing to an overall curved aspect. This sulcal arrangement nears the one detected in T. o. darti in our study.

4. Discussion

4.1. Endocranial volumes

To the best of our knowledge, this current study reports and compares for the first time the ECVs of Plio-Pleistocene South African cercopithecoid taxa, with the exception of extinct Theropithecus, for which ECVs were previously estimated by Martin (1993) and Elton et al. (2001). Our estimates of T. oswaldi ECVs (134–170 cm³, including both T. o. oswaldi and T. o. darti) fit within the fairly wide range estimated by Martin (1993; 154–200 cm³) from three T. oswaldi crania from eastern Africa (Peninj DAT 600/82, DAT 600/83, and Peninj DAT 600/84).
a *T. oswaldi* female, Kanjera BM 32102, a *T. oswaldi* male, and Kanjera BM 14936, a *T. oswaldi* female). In contrast, ECVs of *T. o. oswaldi* (168 cm³ for SK 561) and *T. o. darti* (134 cm³ for MP 222 and 170 cm³ for M 3073) reported in our study are higher than the *Elton et al. (2001)* estimates (150 cm³ for *T. o. oswaldi* SK 561, 122 cm³ for *T. o. darti* MP 222, and 143 cm³ for M 3073; based on regression equations assessed specifically on *Theropithecus*).

The differences between our and previous studies might be explained by the methods used, as we estimate ECVs directly by virtually filling the neurocranium and extracting the endocranial volume rather than packing the braincase with seeds (*Martin, 1993*) or using regression equations derived from the relationship between external cranial dimensions and whole cranial capacity in extant *Theropithecus* and cercopithecoids (*Elton et al., 2001*). Besides being noninvasive, the assessment of ECVs based on high-resolution imaging techniques and virtual reconstruction of endocasts is important for understanding primate paleoneurology, not only because of the more direct means of ECV estimation but also because ECV can be more reliably delimited through the virtual exploration of internal bone structures. In addition, our techniques allow the inclusion of incomplete skulls (e.g., MP 222).

Our current study is focused primarily on methodological development, and hence presents preliminary results. It will need to be extended considerably in the future by integrating a larger sample of extant and fossil cercopithecoids (e.g., a total of 339 and 22 extant and fossil cercopithecoid specimens respectively were sampled in *Elton et al., [2001]*) and considering and testing crucial variables such as sexual dimorphism and allometry. This notwithstanding, in our study, extant *Papio* has the largest ECVs relative to body size among both extant and extinct cercopithecoids considered, as is also true for brain weight (*Martin, 1993*). *Macaca* specimens (particularly *Macaca mulatta*) have some of the lowest ECV values for cercopithecoids of ‘medium’ body mass. A similar finding has previously been reported for *Macaca sylvanus* (*Isler et al., 2008*) but, as in the present study, interpretation was hindered by the small sample. The ECVs computed in our study also conform to previous work showing that extant colobines have smaller brains than other cercopithecoids (*Martin, 1993; Isler et al., 2008*). One of the most interesting results in our study concerned ECV in the fossil colobine *C. williamsi*, which grouped with the fossil cercopithecin specimens, and at the upper end of the extant cercopithecoid range. At ~20 kg (*Delson et al., 2000*), *C. williamsi* was much larger than extant African colobines, so it is difficult to make direct comparisons with its closest modern relatives without a full allometric analysis. Nonetheless, smaller brains (as seen in extant African colobines) may be related to folivory (*Martin, 1993*), so the fact that *C. williamsi*, probably a terrestrial forager (*Codron et al., 2005*), groups with the other large Plio-Pleistocene eastern African Cercopithecoids taxa estimated to be smaller (*C. alemayehuhi, C. keroensis, C. meaveae* or bigger (*C. kimeui*) than *C. williamsi* (*Jablonski and Frost, 2010*).

4.2. Taxonomic and evolutionary implications of endocranial organization

In general, the sulcal patterns we observed in the present study confirm to those previously described for cercopithecines (*Connolly, 1950; Falk, 1978*). In *Parapapio*, the organization of the parietal sulci, and especially the position of the central and intraparietal sulci, is consistent across individuals. The taxonomically undetermined specimen STS 538 shares features with the specimens identified as *Parapapio*, consistent with previous tentative assignment based on external cranial morphology (*Heaton, 2006*). The distinction between the gross endocranial morphology of cercopithecoid specimens from Makapansgat Member 4, on the one hand, and from the slightly younger Taung and Sterkfontein Member 4 assemblages, on the other hand, needs to be explained by further investigations of the fossil record, such as testing potential temporal sensitivity of endocranial organization (*Delsom, 1984, 1988; McKee, 1993; McKee et al., 1995*).

Our visualizations also highlighted interesting variation that adds to our knowledge of sulcal patterns in Old World monkeys. In the *T. o. darti* specimen M 3073, the subcentral posterior sulcus in the left hemisphere, linked with the central sulcus, appears similar to those described for *T. o. oswaldi* L 238–29 from Omo (*Falk, 1981*). When comparing *T. o. darti* M 3073 with the other Makapansgat *T. o. darti*, MP 222 (neither of which were available for study by *Falk [1981]*) as well as the forms from Hadar described by *Falk (1981)*, it is evident that considerable variation exists within the subspecies. This variation might overlap with that observed in previous work (*Falk, 1981*) on eastern African *T. oswaldi*. *Falk (1981)* suggested that the strongly curved (‘hook-like’) inferior end of the central sulcus resulted from the merging of the central and subcentral posterior sulci and is derived for *T. o. oswaldi* compared to *T. o. darti*. We suggest that *T. o. darti* from Makapansgat may show a transitional gyration pattern, which could match the appearance of the derived condition back to c. 3 Ma (*Brock et al., 1977; McFadden et al., 1979; Delson, 1984*), rather than to 1.9–2.0 Ma as initially proposed by *Falk (1981)*. Moreover, the ‘hook-like’ configuration is not found among extant geladas, where the subcentral posterior sulcus remains perceptible. Accordingly, based on this potential autapomorphic feature, the divergence of the extant *T. gelada* lineage from the *T. oswaldi* lineage could predate the chronological period represented by Makapansgat Member 4, as proposed by *Jolly (1972)*. However, given that the mechanism for the formation of folding in the primate cortex is not yet fully understood (even if probably related to biomechanical constraints [Van Essen, 1997; Hilgetag and Barbas, 2005; Toro and Burnod, 2005; Toro, 2012; Bayly et al., 2014; Tallinen et al., 2016]), phylogenetic interpretations of sulcal pattern should be considered tentative. It is thus possible that allometric factors influence gyral and sulcal pattern in *Theropithecus*. This has implications for the way in which we interpret the evolutionary relevance of sulcal patterns, particularly since a correlation has been reported between increase in brain size and increase in gyrencephaly in mammal orders (*Pillay and Manger, 2007*). Moreover, because of the mechanisms of gyrogenesis (*Welker, 1990*), variation in developmental processes may also contribute to sulcal patterns in mature individuals. Accordingly, cerebral ontogenetic changes may also play a role in the variation seen in the genus *Theropithecus*, especially given the developmental differences described for extant geladas compared to other papionins (*Swindler and Beynon, 1993*).

Another intriguing finding was the variation we observed in *C. williamsi* endocranial organization. All three specimens included in this study that are assigned to *C. williamsi* shared features with *Colobus*, as revealed by the statistical classification of the well-preserved specimen M 3055 among extant colobines, although the morphoarchitecture of *C. williamsi* endocasts does not mirror the pattern seen in extant colobines: specific colobine-like structures such as the paroccipital sulcus were not identified in our Cercopithecoides sample, even if as pointed out by *Tobias (1987: 746)* “valuable information may flow from the presence of a sulcus or of a convolutional bulge on an endocast, whereas the absence of an impression may be of dubious morphological significance.” One specimen, MP 36, also showed a configuration of the inferior part of the central sulcus very similar to the *T. o. darti* specimen M 3073. MP 36 is mainly represented by the neurocranium and meager
tooth fragments, and has variously been attributed to Simopithecus darti (by R. Broom and J.S. Jensen; see Freedman [1957]), Pp. broomi (Freedman, 1957; Eisenhart, 1974), and, most recently, C. williamsi (Fourie et al., 2008). Given the sulcal similarities we observed between MP 36 and M 3073, it is possible that MP 36 is actually T. o. darti, although more research to illuminate species-specific variation in cercopithecoids would be desirable. Additional research would also be useful to help understand the evolutionary history of sulcal patterns in colobines. The extant colobine sulcal pattern as described by Falk (1981) in African and Asian taxa, characterized notably by the presence of an arched intraparietal sulcus and the divergence of the principal sulcus from the orbital border, among other aspects, is present in Mesopithecus pentelicus (Radinsky, 1974), a Eurasian Pliocene colobine. Recent work has suggested that C. williamsi is a definitive member of the African colobine clade (Frost et al., 2015), implying that modern African colobines are more distantly related to Mesopithecus than they are to C. williamsi. Thus, similarities in the sulcal patterns of Mesopithecus and extant African colobines must either have arisen convergently, or Cercopithecoides shows sulcal morphology that is derived relative to other colobines. Our knowledge of this would also be enhanced further by including C. haussigi (Mckee et al., 2011), and indeed other large African colobines, into analyses.

It must also be considered that sulcal pattern may be linked to function, and it is possible that functional convergence may explain some of the similarities between C. williamsi and papionins. Based on sulcal pattern, Falk (1981) hypothesized that T. oswaldi had a relatively expanded cortical somatic sensory and motor face representation compared to the geladas, potentially due to the specialization for mastication of abrasive food. However, making interpretations of function from sulcal pattern is problematic: some inconsistencies in correspondence between sulcal and cytoarchitectural areas have been identified, meaning that the cerebral areas delimitated by sulci on the external cortical surface do not systematically coincide with functional areas (Amunts et al., 1999; but see; Fischl et al., 2008). Hence, very little can be reasonably inferred about function from our data.

5. Conclusions

Despite the relative abundance of nearly complete cercopithecoid neurocrania in the paleontological assemblages, endocranial condition has not yet been fully detailed in the South African Plio-Pleistocene records, mainly because of the difficulties related to the extraction of fossil endocasts. Through non-destructive X-ray radiation based high-resolution 3D tomography imaging techniques, we successfully reconstructed virtual endocrania from a representative sample of fossil cercopithecoids and reported ECVs for the first time, as well as morphological and structural variations. In particular, we contributed more information regarding the variation in sulcal pattern in Theropithecus. As previously suggested in the eastern African context, the Theropithecus fossil lineages present specific derived sulcal patterns, suggested to be useful for taxonomic identification, especially of isolated neurocrania. The identification of this landmark feature in the Makapansgat record supports the possibility of the divergence between the Theropithecus fossil lineages and T. gelada prior to 3 Ma. Our investigation of C. williamsi endocasts reveals an ECV and sulcal pattern similar to the papionin condition. Given that Cercopithecoids, a committed terrestrialist, differed substantially from the arboreal existence observed in its living counterparts, similarities with papionins in terms of cortical organization might potentially support the hypothesis of an extinct colobine taxon that was adaptively different from modern African colobines.

Besides traditional analyses of the outer cranial morphology, high resolution virtual imaging of fossil primate endocasts allowing the automatic detection of neocortical relief coupled with deformation-based models and statistical analyses have the potential to add a significant amount of taxonomic and phylogenetic information. Further research in virtual endocranial paleoprimatology to be developed at a continental scale, including fossil specimens from the rich eastern African cercopithecoid-bearing sites and notably representatives of the Theropithecus genus (Jablonski, 1993; Frost, 2001, 2007; Frost and Delson, 2002; Frost and Alemseged, 2007; Jablonski and Leakey, 2008; Gilbert et al., 2011; Frost et al., 2014), would better clarify the polarity, intensity, and timing of the evolutionary changes among cercopithecoid lineages.

Acknowledgments

We are indebted to S. Potze ( Pretoria), B. Zipfel (Johannesburg), J. Cuisin (Paris), G. Fleury (Toulouse), and W. Wendelen (Tervuren) for having granted access to fossil and comparative material under their care. We also thank K. Carlson and T. Jashashvili (Johannesburg), G. Clément and M. Garcia-Sanz (Paris), L. Bam ( Pretoria), and D. Maret and E. Coudrais (Toulouse) for (micro-X-ray) tomographic scans. For scientific contribution and/or for discussion and comments to the results presented in this study, we are especially grateful to E. Delson (New York), D. Ginibre (Toulouse), J. Heaton (Birmingham), N. Jablonski (University Park), O. Kullmer (Frankfurt), R. Macchiarelli (Poitiers & Paris), M. Nakatsukasa (Kyoto), L. Pan (Toulouse), and C. Zanolli (Toulouse). The present version greatly benefited from the comments provided by the Editor, the Associate Editor, and three anonymous reviewers. The French research federation FERMaT (FR3089), the National Research Foundation (NRF), and Department of Science and Technology (DST) of South Africa are acknowledged for providing micro-X-ray tomography laboratory facilities. This work was granted access to the HPC resources of CALMIP supercomputing center under the allocation 2015-[P1440] attributed to the AMIS laboratory. Research supported by the Center of Research and Higher Education (PRES) of Toulouse, the Midi-Pyrénées Region, and the French Ministry of Foreign Affairs.
