Keywords: Silver Speciation Sorption Quartz sand Pyrite Langmuir-type model Reduction Colloids

ABSTRACT

In order to better understand the fate of the toxic element Ag(I), sorption of Ag(I) was studied from batch experiments, at different pHs (2-8) and at 298 K. A pure quartz sand (99.999\% SiO\textsubscript{2}) and “natural” quartz sand (99\% SiO\textsubscript{2}, and traces of Fe, Al, Mn (hydr)oxides, of clays and of pyrite) were used as sorbents. The Ag(I) sorption behavior depends strongly on pH with isotherm shapes characteristic of Langmuir type relationship for initial Ag concentration [Ag(I)]\textsubscript{0} range between 5.0 \times 10^{-7} and 1.0 \times 10^{-3} M. Even if the Ag(I) sorption capacity on pure quartz sand is very low compared to the natural quartz sands, its affinity is rather high. From speciation calculations, several sites were proposed: at pH 4, 6 and 8, the first surface site is assumed to be due to iron (hydr)oxides while the second surface site is attributed to silanols. At pH 2, sorption of Ag(I) was assumed to be on two surface sites of iron (hydr)oxides and a third surface site on silanol groups. Even if the sand is mainly composed of silica, the trace minerals play an important role in sorption capacity compared to silica. The conditional surface complexation constants of Ag(I) depend on pH. On the other hand, it is shown that the Ag speciation depends strongly on the history of “natural” quartz sand due to initial applied treatment, little rinsing or longer washing. In the presence of low amount of pyrite, strong complexes between Ag(I) and sulfur compounds such as thiosulfates due to oxidative dissolution of pyrite are formed what decreases Ag sorption capability. SEM EDS analyses highlighted the surface complexation precipitation of AgS and Ag(0) colloids which confirmed the important role of pyrite on Ag(I) speciation.

1. Introduction

Interactions of heavy metals at liquid liquid and liquid solid interfaces have been largely studied by the scientific community due to their role in the understanding of environmental pollution owing to the various human activities: metallurgy, dentistry, chemistry, nuclear industry, paint and batteries, and agricultural habits such as the use of fertilizers, fungicides and other pesticides. To prevent migration of heavy metal pollutants in wastewater, contaminated soil and solid waste, knowledge of mechanisms controlling transport and transfer of metals which occurs at the solid liquid interface is thus a prerequisite. The possible mechanisms are numerous: precipitation, dissolution, sorption, complexation, oxidation-reduction, etc. Silver is considered as a toxic metal either if present in cationic form, Ag(I), or as nanoparticles, mainly Ag(0) \cite{1,3}. Anthropogenic activities (mining, steel mills, cement plants, burning fossil fuel, nuclear, biocides, etc.) have been among the main sources of Ag(I) in natural systems \cite{1,5}. Nowadays its biocide effects when used as nanoparticles are considered as very strong and explained why Ag is very often present in its colloidal forms in the environment \cite{1}. The maximum silver concentration in drinking water is recommended at 50 \mu g L\textsuperscript{-1} by the World Health Organization (1975) and limited at 10 \mu g L\textsuperscript{-1} in the European Union (98/83/CE). Silver is also included in the US EPA list of priority toxic pollutants. Thus, to avoid pollution, understanding the phenomena of sorption is essential to predict the speciation of Ag(I) and Ag nanoparticles in environmental system and matrix \cite{1}.

Ag(I) can form complexes with ligands present in the environment. It may, in the case of Ag(I), form stable complexes with ammonia, cyanide, thiosulfate, and halide. Silver sulfide, AgS, is one of the most insoluble silver salts. However, the solubility of
the salt can change with the presence of organic or inorganic ligands which form complexes depending on pH, ionic strength, redox conditions, etc. Few studies have reported on Ag(I) sorption on different natural minerals [6, 9].

For example, the surface of pyrite is known for its properties of adsorption and retention of precious metals such as gold, silver, platinum and also mercury [10]. Moreover, the oxidative dissolution of pyrite releases aqueous SO$_4^{2-}$, Fe(II) and Fe(III) in acidic medium and SO$_4^{2-}$ and iron (hydr)oxides FeOOH(s) in basic medium [11, 12]:

$$2\text{FeS}_2 + 7\text{O}_2 + 2\text{H}_2\text{O} \rightarrow 2\text{Fe}^{2+} + 4\text{SO}_4^{2-} + 4\text{H}^+$$ (1)

$$2\text{Fe}^{2+} + 0.5\text{O}_2 + 2\text{H}^+ \rightarrow 2\text{Fe}^{3+} + \text{H}_2\text{O}$$ (2)

$$2\text{FeS}_2 + 7.5\text{O}_2 + 7\text{H}_2\text{O} \rightarrow 2\text{Fe}^{2+}(\text{OH})_{3(s)} + 4\text{SO}_4^{2-} + 8\text{H}^+$$ (3)

Rate law of pyrite oxidation has been reported by Williamson and Rimstidt [13], taking into account the O$_2$ and H$^+$ molalities. Recently, Gartman and Luther III [14] have shown that the oxidation rate of sub micron pyrite in seawater is first order with respect to both O$_2$ and pyrite concentration.

Scaini et al. [6] have worked on the interaction of Ag(I) ([Ag(I)] = 10^{-4} M) with pyrite, at pH 3. Analyses of the solution after reaction have displayed measurable amounts of Fe$^{2+}$. According to their results, the presence of Ag$_2$S and the deposition of metallic silver (XPS and SEM analysis) have been detected on the surface of pyrite. In conclusion they have proposed the following mechanism [6]:

$$\text{FeS}_2 + 8\text{Ag}^{+} + 4\text{H}_2\text{O} \rightarrow \text{Fe}^{2+} + \text{Ag}_2\text{S} + 6\text{Ag}(0) + \text{SO}_4^{2-} + 8\text{H}^+$$ (4)

Ravikumar and Fuerstenau [7] have studied the Ag(I) sorption on cryptomelane, a manganese oxide. Sorption depends on surface chemistry of oxide and chemical composition of solution (e.g. pH). They have proposed an ion exchange reaction mechanism between Ag(I) and potassium [7]. In addition, Dzombak and Morel [8] have estimated many surface complexation constants of several metals with hydrous ferric oxide (HFO). They have concluded that the adsorption capacity of Ag(I) is higher at basic pH and that sorption is controlled by formation of monodentate surface complex. For the strong surface sites (s), Ag sorption is described by the following surface complexation reaction:

$$\text{Ag}^{+} + \equiv \text{Fe}_s \text{OH}_s = \equiv \text{Fe}_s \text{OAg} + \text{H}^+$$ (5)

The surface complexation constant being estimated at 10$^{-1.72}$, for 0.1 mM [Ag(I)] (for the weak surface site, the surface complexation constant is 10$^{-5.3}$).

Moreover they have concluded that the behavior of Ag(I) could be controlled by a mechanism of complexation precipitation at high pH and at Ag(I) concentration below 600 µM [8]. Jacobson et al. [9] have studied the Ag(I) sorption on various soils with different organic matter content and composition. In their conclusion they have stated that even if Ag(I) sorption is dominated by organic matter, illicic clays play an important role in retaining Ag(I).

The present work focused on the sorption of Ag(I) on three materials: a pure quartz sand, a washed and rinsed natural quartz sands. The raw natural quartz sand was shown to have small amounts of pyrite, clays and (hydr)oxides of Fe, Mn and Al. The objective was to understand the behavior of Ag(I) in the presence of different sands by identifying possible sorption mechanisms and estimating surface parameters. The sorption isotherm experiments of Ag(I) performed at 4 initial pHs (2–8) were analyzed by XPS and modeled according to Langmuir type isotherms with 1, 2 or 3 sites. In addition, to highlight an area of precipitation, experiments with higher concentrations of Ag(I) (10$^{-2}$ M) at pH 6 were performed. The products of reactions between sand minerals and Ag(I) were confirmed by SEM EDS analysis.

2. Theories

2.1. Langmuir type relationship

The Langmuir model [15] has been developed to study the equilibrium at gas solid interface. Owing to similar shaped isotherms, this model has been extended for probing the sorption phenomena non at liquid solid interface [16]. Some mathematic relationships have been adopted for fitting the experimental data. In this case the solution species, A, can be adsorbed on surface sites of a solid adsorbent $\equiv S$, with a 1:1 stoichiometry and $\equiv SA$, the adsorbat, present at the surface [17]:

$$\equiv S + A \rightleftharpoons \equiv SA$$ (6)

The concentrations of $\equiv S$ and $\equiv SA$ are in mol m$^{-2}$. The equivalent of maximum surface site concentration in experimental conditions (mol m$^{-2}$) is:

$$\Gamma_{\text{max}} = \Gamma_{\equiv S} + \Gamma_{\equiv SA}$$ (7)

For two or more surface sites, $\Gamma_1$, $\Gamma_2$, ...$\Gamma_m$, which correspond to different site affinities, the relationship between the adsorbed and the aqueous concentrations of A can be calculated at equilibrium according to the Langmuir type model [17]:

$$\Gamma = \sum_{i=1}^{n} \frac{K_{\text{ads},i} [A]_{aq}}{1 + K_{\text{ads},i} [A]_{aq}}$$ (8)

where $K_{\text{ads},i}$ is the Langmuir type constant (L mol$^{-1}$), [A]$_{aq}$ is the total aqueous concentration of A (mol L$^{-1}$), $\Gamma$ is the total sorbed concentration of Ag(I) (mol m$^{-2}$), and $\Gamma_{\text{max}}$ is the equivalent of maximum surface site concentration in experimental conditions (mol m$^{-2}$). The parameters, $\Gamma_{\text{max}}$ and $K_{\text{ads},i}$ can be directly estimated, from experimental data with specific software, such as Origin spreadsheet.

The relationship between Langmuir type model and surface complexation is described in more details in the Supporting information.

2.2. Speciation software: MICROQL

The software MICROQL [18, 19] was used for speciation calculations of the adsorption of a given solute on mineral surfaces. The reactions and mass balances which are necessary for calculation are reported as a Tableau in Table S1 [20] (see the Supporting information for more detail about surface acidity and aqueous speciation theories).

3. Materials and methods

3.1. Sorbent materials

Three sorbent materials were used: (i) a pure quartz sand, (ii) a natural quartz sand washed in a column (treatment I) and (iii) the same natural quartz sand rinsed with pure water (treatment II).

3.1.1. Pure quartz sand

This material was purchased from the “Quartz & Silica Company” in Nemours (Seine et Marne, France). It was produced by heating silica at 1000 $^\circ$C and treating with hydrofluoric acid and recrystallizing for purification. According to the company, and to XPS surface analyses, the pure quartz sand is composed of 99.999 % SiO$_2$ at its surface [21]. The specific surface area is rather low,
about 0.033 m² g⁻¹ (N₂/He, 77 K, BET, QSurfM1, Thermo Finnigan), and the range of grain size is between 100 and 620 µm [22].

3.1.2. Natural quartz sand

Natural quartz sand was provided by “Quartz d’Alsace” Company in Kaltenhouse (North of Strasbourg, France). This sand was a natural product which was washed, sieved, and dried at 105 °C by the manufacturer. The mineral composition of sand was studied by Behra [23,24] and contains 99% SiO₂, 1% potassic feldspars, ~0.1% clays (among: kaolinite and illite) and traces of Fe, Mn and Al (hydr)oxides. Some pyrite in the natural quartz sand is also present in cubic and globular forms (Fig. S1a and S1b). From size analysis, it can be shown that the surface and grain size of the sand are very heterogeneous and porous. The grain size median diameter (d_{50}) and characteristic diameter (d_{90}) are approximately 650 µm and 430 µm, respectively [21]. The specific surface area is rather high, about 0.16 m² g⁻¹ (Kr, 77 K, BET) [21] with respect to the grain size distribution. The point of zero charge is about pH 6, showing the presence of metal (hydr)oxides at surface grains [25].

3.1.3. Sand treatment

For sorption experiments, two types of treatment were performed. For the primary experiments and for initial pH of 2, 4, 6, and 8, the sand was washed with demineralized water in a column (treatment I). This treatment lasted approximately 20 days to obtain a constant value of pH (Knick 765 calimatic, Orion Ross combined glass electrode 8102) and conductivity (Knick 703). For other experiments performed at initial pH 6 and at a high concentration of Ag(I), the sand was rinsed with demineralized water for a brief period (~10 min) (treatment II). This treatment resulted in few significant changes of surface. The two sands were then dried in an oven at 40 °C for 4 h and kept at room temperature (20 °C) prior to use in sorption experiments.

According to the composition, this natural quartz sand represents, at a small scale, a sample of aquatic material. This sand was used to characterize the behavior of other pollutants, notably Hg [23,25], TBT [21,25,26], Cd, Pb [27] and As [28]. Kinetic and isotherm experiments of Ag(I) sorption on natural quartz sand (treatment I) have been ever presented by Hernandez and Behra [29] but without discussion of results. In these previous studies, minerals of pyrite have never been highlighted and could be an important aspect for the study of Ag(I) or other metals on natural quartz sand.

3.2. Experimental procedure

The sorption experiments were carried out in batch reactors (polyethylene bottles, sand mass of 5 g, reactor volume of 50 mL, 298 K and no light for avoiding photoreaction of Ag). The range in initial concentration of Ag(I) was between 5.0 x 10⁻⁷ and 1.0 x 10⁻⁶ M. For each given concentration, three reactors contain ing liquid and solid phases, and a blank containing liquid phase only, were prepared for checking the reproducibility of experiments.

A stock solution of 0.10 M Ag(I) was prepared by weighing (Sartorius LA 3105, detection limit > 0.1 mg) AgNO₃ (99.8%, Prolabo 21 572.133), diluted in ultra pure water (18.2 MΩ cm, Milli Q, Millipore). Different Ag(NO₃) solutions were adjusted by successive dilutions from a stock solution. Before adding Ag(I) to a solution of NaNO₃ (ionic strength: 0.010 M), the initial pH, pHᵢ, was adjusted (WTW pH 330) by adding HNO₃ (1.0 M) or NaOH (5.0 M). Solutions were buffered with MES (2 morpholinonethane sulfonic acid monohydrate) (2.0 x 10⁻³ M) for pH 4 and with HEPS (4 (2-hydroxyethyl) piperazine 1 ethane sulfonic acid) (2.0 x 10⁻³ M) for pH 8. When pHᵢ was constant, the volume (50 mL) of AgNO₃ was added in the reactor containing the sand. The reactors were kept in the dark for 4 days (5760 min) and manually agitated twice a day for avoiding grinding of sand grains. The Ag sorbed on sand was calculated from concentration differences between initial and final aqueous concentrations of isotherm experiments and expressed in mol m⁻² using the given specific surface area of each material.

3.3. Aqueous and surface analyses

After experiments, solid and liquid phases were separated for different analyses. Total silver, as ¹⁰⁷Ag and ¹⁰⁹Ag isotopes, were analyzed with an ICP MS (VG Plasma Quad3) or ICP AES (Elan 6000, Perkin Elmer) depending on Ag concentration. Anions were analyzed by anion chromatography ICS 2000 (DIONEX, column: Ion Pac AS11 Analytical (4 x 250 mm) Product No. 044076). This technique quantified the total concentration of fluorides, chlorides, bromides, nitrates, nitrates, phosphates and sulfates for a range of concentration between 1.0 and 50 mg L⁻¹. The pH of solution was also measured after experiments. For some experiments, Fe and Al were analyzed by ICP OES [30].

Qualitative analyses of rinsed sand were performed before and after experiments at pH 6 with a Scanning Electron Microscope (Jeol 6360LV, at LMTG) equipped with an Energy Dispersive X ray Spectrometer (SEM EDS). XPS analyses were performed as described by Bonnissel Gissinger et al. [12].

4. Results

4.1. Ag(I) sorption on pure quartz sand

The Ag(I) sorption isotherm on pure quartz sand are reported for pH 4, 6, and 6, at 298 K in Fig. 1a. There was no change in the pH value during sorption on pure quartz sand. The adsorption capacities of pure quartz sand are very low and the amount of Ag sorbed are not measurable for [Ag] < 0.1 µM. Adsorption shows an asymptotic trend depending on initial pH at high concentration of Ag(I).

4.2. Ag(I) sorption on washed “natural” quartz sand

The Ag(I) sorption isotherms on washed natural quartz sand (treatment I) are displayed for 4 different pHₐ (~2, 4, 6 and 8) in Fig. 1b. Initial and final pH are reported in Table 1. There was no significant change of pH at pHₐ 2. At pH 4 and 6, the pH increased while the pH decreased at pHₐ 8 after sorption of Ag(I). Increasing pHₐ resulted in the increase in Ag(I) adsorption capacities, except for pHₐ ~8 and [Ag]ₐq < 10⁻⁶ M. As observed, the washed natural quartz sand adsorbs more than the pure quartz sand. This could be explained by the presence of trace minerals which would play a very important role in the case of Ag(I) sorption.

Isotherms show a Langmuir type behavior for all pH with an asymptotic trend at high values of [Ag]ₐq. At pHₐ ~4, 6 and 8, the sorption isotherms of Ag(I) on the washed natural quartz sand have the same shape. For low Ag concentrations, the isotherms have a concave form, and for higher Ag concentrations, the isotherms become convex, except at pHₐ ~2.

4.3. Ag(I) sorption on rinsed “natural” quartz sand

Ag(I) sorption isotherm on rinsed natural quartz sand (treatment II) at pHₐ ~6 for initial concentration ranges between 1.0 x 10⁻⁷ and 1.0 x 10⁻⁵ M was plotted together in Fig. 2a. Ag(I) isotherms were different for the two sands. During the experiment, the pHᵢ was 6.12 and decreased to 5.7 ~5.9 after Ag(I) sorption. Aqueous anions were analyzed by ionic chromatography. Sulfate
ions were detected at about $2.6 \times 10^{-5}$ M. At the same time, column experiments with tributyltin have been performed [30]. Analyses of outlet column solutions have shown the presence not only of Fe and Al as Bianchi et al. [27] but also of S to the average concentration of which has been around $1.7 \times 10^{-5}$ M, i.e. the same order of magnitude as in the batch reactors used in this study.

The rinsed sand was then analyzed after Ag(I) sorption by SEM EDS and XPS. Ag was not detectable directly on the silica except at high concentration. At pH 4 and Ag concentration higher than $2.0 \times 10^{-5}$ M, Ag represents around 0.4 atomic percent of the sand surface. From SEM pictures, precipitates of metallic silver (Fig. S2a) and silver sulfide (Fig. S2e) were highlighted and confirmed by EDS spectrum (Fig. S2b and S2f). Clays were observed to have set Ag within their layers. The Fig. S2c depicts the smectite clay or chlorite surrounded by silica. The EDS spectrum (Fig. S2d) corresponding to this clay sample exhibits strong peaks correlating to Si, Al, O, Ag and weak peaks of Fe and Mg.

5. Discussion

5.1. Modeling of sorption data

5.1.1. Pure quartz sand

For modeling sorption data on pure quartz sand, it was assumed that silica sites are the only available sites according to the following surface reactions

$$\equiv Si \text{OH} + Ag^+ \rightarrow \equiv Si \text{OAg} + H^+$$ (9)

The $pK_a$ values used for modeling are $pK_{a1} = 0.95$ and $pK_{a2} = 6.95$ for silica [31].

Estimated surface site concentrations and Langmuir type constants are reported in Table 1. Calculated isotherms show a good fit to the sorption data except at pH 4 and $[Ag]_{aq} < 0.5 \times 10^{-5}$ M (see Fig. 1). This confirmed the hypothesis that only one type of
surface sites is necessary for describing Ag(I) sorption on this sand. The values of sorption capacity, $\Gamma_{\text{max}}$ (Table 1) show that the surface site density of silica is very low. This result is in agreement with the work of Malati et al. [32] who have found an Ag(I) sorption capacity of 0.03 $\mu$mol m$^{-2}$ at pH 5 on precipitated silica, the specific surface area of which was however very high, 149 m$^2$ g$^{-1}$. The surface complexation constants estimated from our data are very high (Table 1), what shows a strong affinity of Ag(I) to the pure quartz sand.

5.1.2. “Natural” quartz sand

According to natural quartz sand composition, the surface sites for metal cations could be silica, Fe, Al or Mn hydr(oxides), clays, and even pyrite. During treatment I applied to the sand, some pyrite and clays were probably dissolved and leached with the washing water. These minerals were not highlighted in the washed natural quartz sand by SEM EDS. Then, for modeling sorption data, it was assumed that iron (hydr)oxides were the primary surface sites and that silica acted as secondary surface sites (Eq. (9)). At pH 2, a third site was necessary for optimizing the fitting with experimental data and assumed to be present on iron (hydr)oxides [33].

The postulated chemical reaction for Ag(I) reacting with iron (hydr)oxide surface sites is the same as used by Dzombak and Morel [8], i.e.:

$$\text{Fe(OH)} + \text{Ag}^+ \rightleftharpoons \text{FeOAg} + \text{H}^+ \quad (5a)$$

The $pK_a$ values for iron (hydr)oxides used for modeling are $pK_{a1} = 6.60$ and $pK_{a2} = 9.25$ [17].

From calculations, it was shown that two sorption sites were sufficient to describe the experimental data at pH $\sim$ 4, 6 and 8 whereas three sorption sites were necessary at pH $\sim$ 2 (Fig. 2b). For Ag(I) concentrations above 600 $\mu$M and a high pH corresponding to a change in slope, both surface complexation and surface precipitation are assumed [8,33].

A good correlation exists between experimental data and modeling. However, estimated values of surface complexation constants were a function of pH (Fig. 3). Thus, the behavior of Ag(I) cannot be predict for all experimental conditions with these values.

Moreover, for each site, the sorption capacity, $\Gamma_{\text{max}}$, increased with increasing pH (Table 1). For example, the sorption capacity of the first site is 0.022 $\mu$mol m$^{-2}$ for pH $\sim$ 2 and 1.56 $\mu$mol m$^{-2}$ for pH $\sim$ 8. This suggests that sand washed with water in a column behaves like a cation exchanger for weak acids [16]. The pH variations due to Ag(I) sorption are listed in Table 1. The pH variation with the washed quartz sand was detected while the pH change for pure quartz sand was not measurable. The measurable variation of pH with natural sands can be due to two mechanisms at least: (i) dissolution of minerals present at the surface of the “natural” sands and (ii) the exchange between H$^+$ and Ag$^+$ during sorption at the surface sites. At pH $< 6$, the increase in pH after Ag(I) sorption could be due to the dissolution of metallic (hydr)oxides (Fe, Al and Mn), reactions which need H$^+$ ions. This is consistent with the results of both Bianchi et al. [27] who have found aqueous Fe and Al after agitating this sand during 1 h at pH 4, and Rafidiariason [30]. At pH 8, the pH decreased after Ag(I) sorption. In basic medium, dissolution of metallic (hydr)oxides always occurs in addition to the dissolution of some pyrite remaining after treatment I.

5.2. Influence of sand treatment on Ag(I) speciation

Due to mineral dissolution, the Ag(I) speciation could be different during the sorption on the two “natural” sands. The experimental conditions were the same except the washing treatment before sorption experiments. As shown by Bianchi et al. [27] and Bueno et al. [25], the treatment applied to the sand may change its surface reactivity. With respect to Ag(I), this change would imply different possible interactions with sand surface. The possible minerals of the sand, which can dissolve during treatment con
dictionaries, are Al, Fe and Mn (hydr)oxides along with pyrite. The presence of sulfates in the reactor after experiments can be due to pyrite dissolution because the only other mineral containing sulfates was the barite which was assumed insoluble in studied conditions. Another fact in favor of pyrite dissolution was the characterization of metallic silver (Fig. S2a and S2b) and silver sulfur precipitate by SEM EDS (Fig. S2e and S2f). This is consistent with the analyses and explanations of Scaini et al. [6] and Eq. (4) showing that redox reaction occurring at the surface of pyrite between sulfur and Ag(I) leads to both the reduction of Ag(I) to Ag(0) and of S( I) to S( II) followed by precipitation of Ag2S, and the oxidation of S( I) to S(VI). The presence of SO4\(^{2-}\) in aqueous solution could have been provided by the interaction of Ag(I) with pyrite. According to the mechanism proposed by Eq. (4) [6], the formed species in solution are SO4\(^{2-}\), Fe3+ and H+. It has been reported that at pH 6, the oxidation of Fe(II) to Fe(III) in pyrite is fast and that the precipitation of Fe(III) (hydr)oxides is possible [12]. The surface of pyrite is then more heterogeneous and consists of Fe(II) and Fe(III) (hydr)oxides. When protons are combined the pH dropped rapidly to 4 from an initial pH between 5 and 10. At pH 4, pyrite is highly reactive and unstable due to its high oxidizing capacity and is oxidized to Fe(III) and SO4\(^{2-}\).

The concentration of the sulfur compound most oxidized, SO4\(^{2-}\), is about 2.6 × 10^{-3} M but prior to anion chromatography measurements, sulfur had to be in other forms like sulfites, sulfides and/or thiosulfates during oxidative dissolution of pyrite [12,34]. The presence of these sulfur compounds can strongly change the aqueous Ag(I) speciation. Indeed Ag(I) can form more or less stable complexes with sulfur species such as SO4\(^{2-}\), S\(^{2-}\), SO3\(^{2-}\) and S2O3\(^{2-}\) (see list of stability constants in Table S2) [35]. According to Eqs. S30 to S34, Ag(I) forms three different complexes with S2O3\(^{2-}\) depending on physical chemical composition of aqueous solutions. The formation of such aqueous Ag(I) complexes strongly decreases the free aqueous Ag\(^{+}\) resulting in a decrease in the possible interactions with surface sites. Assuming that the initial concentration of S2O3\(^{2-}\) is about 2.6 × 10^{-3} M, free Ag(I) concentration was calculated for each experiment. The data of Ag(I) sorption were then plotted vs. the free Ag(I) concentration calculated by taking into account S2O3\(^{2-}\) concentration. In this case, both data sets of Ag(I) sorption at pH 6 were superimposed. Results were similar if complexes between Ag(I) and S( II) which was assumed in the system. However no effect was highlighted by taking into account aqueous complexation of Ag(I) with SO4\(^{2-}\) or SO3\(^{2-}\). According to these results, it appears that the change in mineral composition of the surface of “natural” quartz sands due to its aging during treatment plays an important role in surface reactivity and interactions. During the treatment I (20 days), a large part of pyrite was dissolved and the dissolved products were exported to the outlet of the column and then lost. In contrary, after the treatment II, minerals stayed in studied system and then played an important role in the Ag(I) speciation. This point is very important in the case of aquifer which evolves slowly with time, e.g. in the case of nuclear waste disposal. Indeed, the dissolution of some minerals can be significant with percolating water and change readily the speciation of heavy metals such as Ag and thus their fate in the nearby environment.

So far, it was assumed that the surface sites of iron (hydr)oxides and silica were the main actors for controlling the surface complexation. Indeed, the role of clays was minimized. The clays present in the “natural” sand can thus play a more important role than silica in the sorption of Hg(II) even if the clays are present in small proportion. With respect to the Ag(I), the SEM EDS analysis (see Fig. S2c and S2d) show that interactions between clays and Ag would occur which is consistent with the works of Jacobson et al. [9]. In our case, modeling with silica and iron hydroxides was sufficient but it would be interesting to study materials containing a larger proportion of clays.

### 5.3. Effect of HEPES at basic pH

In literature, HEPES has been used for many chemical and biological studies because of its known neutrality towards the metal ions [36,37]. However, the study of Vasconcelos et al. [38] have shown that HEPES was able to bind Cu(II) when HEPES was in large excess (2000 < HEPES/Cu < 10000) at pH 8. They have reported that the importance of complexation was even more pronounced when the Cu concentration was low. HEPES represents a weak zwitter ionic acid at low pH with low affinity for cation. Although for high pH, the affinity between HEPES and cations increases due to the deprotonation of the acid [39]. According to these studies and stability constant estimation for Cu(II) [40], a complexation reaction between HEPES and Ag(I) could thus explain the low Ag(I) sorption at pH 8 with Ag(0) colloids, the mobility of which has to be investigated at larger scale to evaluate their possible migration, can be formed at the surface of sand grains. Ag is an interesting probe since its reactivity depends strongly on redox conditions. Other metals which are present in waste such as nuclear waste are also strongly redox dependent. Thus, it is obviously shown in this study how traces of pyrite which control redox conditions have to be taken into account for avoiding great mistakes in modeling transport at large scale.

### 5.4. Some input for environmental applications

From this study, it was shown the role of the surface composition of sand in the behavior of a trace metal such as Ag. Depending on local environmental conditions, Ag can react and be either sorbed as a surface complex on different minerals such as iron (hydr)oxides, silica and clays, or precipitated due to the presence of traces of pyrite and its redox dissolution. In the latter case, the implications may be important with respect to environmental systems: first some S2O3\(^{2-}\) or S( II) which are formed may dramatically change the Ag speciation, by increasing aqueous Ag concentration and in turn Ag mobility; and secondly some Ag(0) colloids, the mobility of which has to be investigated at larger scale to evaluate their possible migration, can be formed at the surface of sand grains. Ag is an interesting probe since its reactivity depends strongly on redox conditions. Other metals which are present in waste such as nuclear waste are also strongly redox dependent. Thus, it is obviously shown in this study how traces of pyrite which control redox conditions have to be taken into account for avoiding great mistakes in modeling transport at large scale.

### 6. Conclusions

The main objective of this study was to better understand the behavior of Ag(I) in the presence of a natural sand mainly composed of quartz but having some natural impurities such as clays, traces of iron (hydr)oxides and pyrite. Sorption results were compared to a pure quartz sand in order to clearly identify the different Ag(I) adsorption sites. The sorbed Ag concentration is strongly dependent on pH with isotherms characterized by superimposition of Langmuir type isotherms for initial Ag(I) concentration range between 0.5 × 10^{-6} and 1.0 × 10^{-3} M. From experimental data fitting taking into account speciation calculation, several sites are proposed.

At pH 4, 6 and 8, the first surface site is assumed to be due to iron (hydr)oxides while the second surface site is attributed to silanols. At pH 2, sorption of Ag(I) would take place on two surface sites of iron (hydr)oxides and a third surface site on silanol groups. Moreover the presence of pyrite, which was highlighted by aqueous sulfates due to its redox dissolution, is assumed to control part
of Ag behavior, as shown by Scaini et al. [6]. In such heterogeneous and natural system, iron (hydr)oxides, sulfates, and sulfur compounds can react with Ag(I) and in turn control its reactivity both in the aqueous phase and at the solid liquid interface. The possible reactions with ligands such as thiosulfates can explain the fate of Ag(I) sorption when pyrite is still present, even at a low level. SEM EDS analyses proved the assumption of precipitation of Ag sulfur species and surface precipitation of metallic Ag, for high initial concentrations of Ag(I) (>10^{-3} M). On the other hand, XPS chemical surface analysis confirmed shape of complex sorption isotherm from the point of view of the solid surface.

Consequently, we showed that all the minerals, even those present at low surface concentration, can control the transfer of trace compounds. The main issue is that it is absolutely necessary to get the best knowledge of their speciation and sorption mechanisms at atomic scale for reactive transport modeling at larger scale, e.g. for waste disposals such as radioactive nuclear compounds.

For improving the knowledge of the Ag(I) behavior in the environment, further research would be necessary to quantify the influence of the pyrite dissolution kinetics [13,14] and look more closely at the contribution of other minerals such as clays in the Ag(I) sorption in a large scale transport modeling.

Acknowledgments

We thank T. Aigouy (Géosciences Environnement Toulouse (GET), Université Paul Sabatier, CNRS, IRD, OMP, Toulouse, France) for the SEM images, M. Bueno (IPREM/LCABIE, Pau, France) for the ICP AES analysis, the GET for ICP MS analysis, J. Lambert and J.J. Ehrhardt (LCPME, CNRS, Nancy) for XPS analyses, and H. Rafidia rison. The major part of experiments was performed at the IMF Strasbourg. MAHC was supported by a grant from SEP CONACYT IPN.

SI includes two figures and two tables in six pages
**Surface acidity and surface complexation.** The functional groups (-OH, -COOH, -NH₂, -SH) of solid surface become weak acids or bases according to the pH and can be represented by two reactions with two pKₐ:

\[
\equiv \text{S-OH}^+ \quad \leftrightarrow \quad \equiv \text{S-OH} + \text{H}^+ \quad ; \quad K_{a1}^S = \frac{\{\equiv \text{S-OH}\}}{\{\equiv \text{S-OH}^+\}} \tag{S1}
\]

\[
\equiv \text{S-OH} \quad \leftrightarrow \quad \equiv \text{S-O}^- + \text{H}^+ \quad ; \quad K_{a1}^S = \frac{\{\equiv \text{S-O}^-\}}{\{\equiv \text{S-OH}\}} \tag{S2}
\]

where \(\{\equiv \text{S-OH}\}\) is the concentration of surface sites (mol m⁻²), \(K_{a1}^S\) and \(K_{a2}^S\) are the apparent constants of acidity.

The surface complexation occurs when a metal cation reacts with an anion which functions as an organic ligand and forms covalents bonds (10). Surface sites are ligands against to metal cations \(M^+\), forming a monodentate complex \(\equiv \text{S-OM}\):

\[
M^+ + \equiv \text{S-OH} \quad \leftrightarrow \quad \equiv \text{S-OM} + \text{H}^+ \quad ; \quad K_S^1 = \frac{\{\equiv \text{S-OM}\}}{\{\equiv \text{S-OH}\}} \tag{S3}
\]

where \(K_S^1\) is the equilibrium constant.

The total surface sites are:

\[
S_{\text{max}} = \{\equiv \text{S-OH}^2+\} + \{\equiv \text{S-OH}\} + \{\equiv \text{S-O}^-\} + \{\equiv \text{S-OM}\} \tag{S4}
\]

When eqs S1 and S2 are substituted in eq S4, the equation becomes:

\[
S_{\text{max}} = \{\equiv \text{S-OH}\} \left( \frac{[\text{H}^+]}{K_{a1}^S} + 1 + \frac{K_{a2}^S}{[\text{H}^+]^2} \right) + \{\equiv \text{S-OM}\} \tag{S5}
\]

And if it is assumed that:

\[
\alpha_i = \left( \frac{[\text{H}^+]}{K_{a1}^S} + 1 + \frac{K_{a2}^S}{[\text{H}^+]^2} \right)^{-i} \tag{S6}
\]

Then having \(\{\equiv \text{S-OH}\}\) from eq S3 and eq S5, \(S_{\text{max}}\) will be obtained as follows:
\[ S_{\text{max}} = \left\{ \equiv S-\text{OM} \right\} \frac{[H^+]}{[M^+]^{\alpha_i}} + \left\{ \equiv S-\text{OM} \right\} \] (S7)

After factorization, eq S7 becomes:

\[ \left\{ \equiv S-\text{OM} \right\} = S_{\text{max}} \frac{*K_i^S [H^+]^{-1} [M^+]}{1 + *K_i^S [H^+]^{-1} [M^+] \alpha_i} \] (S8)

**Aqueous solution/speciation.** In the case of a free ligand L complex with M\(^+\), the speciation of M\(^+\) changes (10):

\[ M^+ + L \stackrel{\text{K}_{ML}}{\rightleftharpoons} ML^+ \] (S9)

\[ H^+ + L \stackrel{K_a}{\rightleftharpoons} LH^+ \] (S10)

The total concentration of [M]\(_{aq}\) is:

\[ [M]_{aq} = [M^+] + [ML^+] = [M^+] \left(1 + K_{ML} [L]\right) = [M^+] \alpha^{-1} \] (S11)

Then, eq (S8) can be expressed as:

\[ \left\{ \equiv S-\text{OM} \right\} = S_{\text{max}} \frac{*K_i^S [H^+]^{-1} [M]_{aq}}{1 + *K_i^S [H^+]^{-1} [M]_{aq}} \] (S12)

If it is assumed that:

\[ K_{sS-\text{OM}} = *K_i^S [H^+]^{-1} \] (S13)

Finally, eq (S14) can be obtained:

\[ \left\{ \equiv S-\text{OM} \right\} = S_{\text{max}} \frac{K_{sS-\text{OM}} [M]_{aq}}{1 + K_{sS-\text{OM}} [M]_{aq}} \] (S14)

The relationship between \{\equiv S-\text{OM}\} and [M]\(_{aq}\) is Langmuir-type like, for the formation of a monodentate complex. Here, the electrostatic correction term is not taken into account.
**Solubility product.** A solubility equilibrium exists when a chemical compound in the solid state is in chemical equilibrium with a solution of that compound. For example, solubility equilibrium of solid phase, \(M_nX_{m,s}\), can be expressed as:

\[
M_nX_{m,s} \leftrightarrow nM_{aq} + mX_{aq} ; K_{S0} = \frac{\{M_{aq}\}^n \{X_{aq}\}^m}{\{M_nX_{m,s}\}}
\]  

(S15)

If the solid phase is pure, its activity is fixed to equal 1. The constant \(K_{S0}\), called solubility product, is simplified as follows:

\[
K_{S0} = \left\{M_{aq}\right\}^n \left\{X_{aq}\right\}^m
\]

(S16)
