Received December 11, 2019; Accepted January 27, 2020

The purpose of this study was to prepare and evaluate a new two-step sealing process for a porous and tortuous anodic film, prepared on aluminum alloy (AA) 2024-T3, to ensure anti-corrosion properties. This process involves a cathodic electrophoretic deposition of boehmite particles, followed by a hydrothermal post-treatment. This two-step sealing was evaluated through three industrial tests (dye-spot, continuity and salt spray) and the low frequency resistance. Such sealing of the anodic film on AA 2024-T3 showed promising anti-corrosion behavior, suggesting a real potential interest of this innovative process for future industrial applications.

Keywords: Aluminum, porous anodic film, boehmite particles, electrophoretic deposition, hydrothermal post-treatment, sealing

INTRODUCTION

Due to their good mechanical properties and low density, aluminum alloys (AA), are intensively used in the aircraft industry [1,2], as with AA 2XXX (Al-Cu) or 7XXX (Al-Zn). However, Al-Cu alloys, for instance AA 2024, show a low corrosion resistance [3,4]. They therefore require an additional corrosion protection, usually obtained by (electro) chemical processes (i.e. typically anodizing and sealing), usually involving chemical solutions including hexavalent chromium-based compounds. Such compounds are known to be classified as being both highly toxic and carcinogenic and their use is limited by recently adopted European standards (REACH). So, to protect AA 2024 for instance, new alternatives have been studied and developed, such as new anti-corrosion coatings prepared via the sol-gel route [5], with corrosion inhibitors [6-10], as well as new green sealing of anodic films [11,12]. Electrophoretic deposition (EPD) of nanoparticles, from organic or aqueous media, could provide an interesting alternative since it is simple and cheap. In this process, particles migrate under the influence of an electric field and are deposited onto an electrode [13,14]. Organic media are usually used [15,16] due to their wide voltage range of electrochemical stability. For instance, Fori et al. [17,18] successfully filled a porous anodic film prepared on AA 1050 using SiO₂ nanoparticles dispersed in an isopropyl alcohol solution. But, for environmental reasons, the aqueous medium appears to offer a good alternative to avoid pollution. Despite a limited cell voltage due to water electrolysis, some previous studies [19-21] showed a significant incorporation of nanoparticles (SiO₂ and PTFE and AlOOH respectively) inside porous anodic films prepared on aluminum substrates. However, these results were obtained on pure aluminum substrates (99.99 % and 99.5 %) with anodic films showing straight pores, contrary to the tortuous porosity obtained when AA 2024 is anodized. Moreover, in previous studies [19-21], phosphoric acid-based electrolytes are used to perform anodizing to obtain the largest main pore diameter. However, the usual hydrothermal sealing of such anodic films prepared in phosphoric acid-based electrolyte is problematic [22] as compared with other types of anodic films.

There are now two main challenges:
- the first is to deposit nanoparticles on, and ideally in, the tortuous anodic film prepared on AA 2024 substrate,
- the second is to study a new process to seal the anodic film prepared in phosphoric acid-based electrolyte.

The present work aimed to develop a two-step sealing process for a tortuous anodic film prepared by anodizing of AA 2024-T3 in a phosphoric acid electrolyte. This sealing is implemented by direct electrophoretic deposition of boehmite nanoparticles dispersed in an aqueous solution on/into a tortuous anodic film, followed by a hydrothermal treatment. The resulting coatings are then characterized by FEG-SEM observations, and

evaluated through the low frequency resistance (50 mHz) – a good approximation of the polarisation resistance –, as well as using three standard industrial tests, i.e. salt spray, loss of absorptive power and continuity.

**EXPERIMENTAL**

**Preparation**

An aluminum alloy 2024-T3 substrate (compound of 4.5 % Cu, 1.5 % Mg, 0.6 % Mn, 0.2 % Fe, 0.08 % Zn, 0.06 % Si, 0.01 % Cr and 0.03 % Ti) was prepared following a three-step procedure (degreasing, etching and acid neutralization). Firstly, the aluminum sheet (20 x 20 x 1 mm or 80 x 1250 x 1 mm for industrial tests) was degreased using ethanol. The sample was then cleaned firstly in an alkaline aqueous solution (sodium triphosphate and borax) for 20 min at 60 °C (reaction 1).

$$\text{Al}_2\text{O}_3 + 2\text{OH}^- \rightarrow 2\text{AlO}_2^- + \text{H}_2\text{O} \quad (1)$$

Secondly, sample was then immersed in a sulfonitro-ferric acidic solution for 5 min at room temperature (reaction 2).

$$\text{Al}_2\text{O}_3 + 6\text{H}^+ \rightarrow 2\text{Al}^{3+} + 3\text{H}_2\text{O} \quad (2)$$

After being rinsed in deionized water (10⁶ Ω.cm), the aluminum sheet was used as an anode and a lead plate (50 x 40 x 2 mm) as a cathode. The specimen was anodized at constant voltage (70 V for 60 min) in a phosphoric bath (40 g.L⁻¹, i.e. 0.48 mol.L⁻¹) at 25 °C (reactions 3 and 4). Finally, the obtained anodic film was fully rinsed in deionized water.

$$\text{Al} \rightarrow \text{Al}^{3+} + 3\text{e}^- \quad (3)$$

$$2\text{Al}^{3+} + 3\text{O}^{2-} \rightarrow \text{Al}_2\text{O}_3 \quad (4)$$

The first step of the sealing process involved a constant cathodic electrophoretic deposition of boehmite particles dispersed in an aqueous solution. A colloid suspension of boehmite nanoparticles in aqueous media was initially synthesized. This suspension was prepared by hydrolysis of an aluminum alkoxide following the Yoldas process [23] (reaction 5).

$$\text{Al}([\text{OCH(CH}_3]_3\rangle + \text{H}_2\text{O} \rightarrow \text{AlOOH} + 3\text{C}_3\text{H}_7\text{OH} \quad (5)$$

An excess of deionized water (H₂O/Al = 100) at 85 °C was then immediately added to 25.3 g of aluminum tri-sec-butoxide (Al(OC₃H₇)₃) while stirring for 15 min. The white sol obtained was peptized by adding 0.2 mol of nitric acid (HNO₃) per mole of alkoxide to improve particle dispersion. The mixture was then continuously stirred at 85°C for 24 h. The final concentration was around 0.5 mol.L⁻¹.

Electrophoretic impregnation of particles was then performed (10 V, 15 min) with the anodized aluminum substrate as the cathode, while a lead foil, located at about 2.5 cm from the cathode, was used as the anode. After being air dried for about 30min, a hydrothermal post-treatment (deionized water at 98 °C, 2 h) was performed as the second sealing step.

**Characterizations and industrial tests**

Surface and cross-sectional views of the coatings were performed using a Field Emission Gun Scanning Electron Microscope (FEG-SEM JEOL JSM 6700F).

The Stokes diameter of the nanoparticles and zeta potential of the particles were measured by Dynamic Light Scattering using a ZS90 Malvern nanosizer with zetasizer software.

The low frequency resistance (R_LF) of the samples was monitored for 240 h in a solution of NaCl (0.05 mol.L⁻¹) and Na₂SO₄ (0.5 mol.L⁻¹) at room temperature. A low concentration of chloride was chosen to limit the rapid corrosion attack, while sodium sulphate was chosen as a supporting electrolyte. A three-electrode electrochemical cell was used, with a platinum foil as a counter-electrode and a saturated calomel electrode as the reference electrode. The low frequency resistance was measured using an SP-150 BioLogic Science Instrument. It corresponds to the real part of the impedance measured at 50 mHz at open current potential; a RMS voltage amplitude of ± 50 mV_{ref} was applied.

Loss of absorptive power of the anodic films was evaluated by a dye-spot test according to ISO 2143 standard, while their continuity was evaluated with an acidic copper solution according to NF A 91410 standard. Additionally, salt spray tests were conducted for 24 h, according to EN ISO 2143 standard.

**RESULTS AND DISCUSSION**

**After anodizing**

**Characteristics of the bare anodic film**

FEG-SEM views (Figure 1) show that the bare porous anodic film (i.e. before electrophoretic deposition) typically has a thickness of 1.2 ± 0.3 μm. Although this thickness is low, the continuity test is compliant (Table 1) and so attests that the resulting anodic film is homogeneous and evenly covers the whole metal substrate.

FEG-SEM views (Figure 1) additionally show that the porosity is extremely tortuous, much more so than the porosity obtained using purer 1050 aluminum alloy, in agreement with previous studies [24,25]. Despite the real difficulty in distinguishing the pores, their average diameter was estimated to be in the range of 30-50 nm. Unsurprisingly in this case, Grade 2 is obtained with a dye-spot test (Table 1), meaning that ink is impregnated into pores of the anodic film, indicating that the pores are not closed.

**Corrosion behavior of the bare anodic film**

Evaluation of the low frequency resistance was then performed in a solution including NaCl (0.05 mol.L\(^{-1}\)) and Na\(_2\)SO\(_4\) (0.5 mol.L\(^{-1}\)), as a function of the immersion time (Figure 2). In comparison with the raw substrate, the anodized substrate shows a high low frequency resistance (about \(1x10^5 \Omega\cdot\text{cm}^2\)) at the beginning of immersion (\(t = 0 \text{ h}\)), proving the positive intake of the anodic film against corrosion. However, its resistance decreases and reaches a minimum (at about \(1x10^3 \Omega\cdot\text{cm}^2\)) after 100 h of immersion (i.e. more than four days), meaning that the chloride corrosive ions penetrate through the barrier layer. This result is explained mainly by the opened pores and the thinness (1.2 ± 0.3 µm) of the bare anodic film, especially its barrier layer (lower than 100 nm). After 100 h, the bare anodic film shows the same behavior as the substrate, corrosion being generalized and the anodic film failing to further protect the AA substrate.

**After the two-step sealing process**

**Characteristics of the sealed film**

Diffusion Light Scattering analysis showed an average hydrodynamic diameter for the boehmite particles equal to 35±15 nm, while from zeta potential measurement it came out at \(+2.7x10^{-4} \text{ cm}^2\cdot\text{V}^{-1}\cdot\text{s}^{-1}\) as particle electrophoretic mobility. This positive value shows that it is possible to perform a cathodic electrophoretic deposition (here at 10 V), thus avoiding any further oxidation of the metal substrate, i.e. electrodissolution or over-oxidation of the aluminum [26].

![Fig. 2. Low frequency resistance values as a function of the immersion time](image)
F. Caubert et al.: Electrophoretic deposition of boehmite particles to improve the anti-corrosion…

FEG-SEM views (Figure 3) show that electrophoresis alone induced a mainly top-surface deposit, although some of the smallest particles (about 20 nm) could be incorporated into the pores (30-50 nm).

The influence of the second sealing step, i.e. hydrothermal post-treatment (after the EPD), was then studied. FEG-SEM views (Figure 4) show complete sealing of the anodic film, both inside and on the top of the anodic film. On its top surface (Figure 4b), a typical “sand rose” structure is observed, attesting to the aluminum hydroxide formation. The continuity test gave a correct result (Table 1), meaning that the film is homogeneous and crack-free. In addition, after hydrothermal post-treatment, Grade 0 is obtained using the dye-spot test, since no color persists at the surface after removal of the dye-spot.

This result, i.e. complete sealing of the porosity, tends to prove either modification of particles on and inside the anodic film, or the film’s transformation under hydrothermal conditions. To test these hypotheses, the same hydrothermal treatment was performed directly on the bare anodic film, i.e. without electrophoretic deposition. FEG-SEM views (Figure 5) show that no change can be observed in comparison with the bare anodic film (Figure 1). Moreover, while the industrial continuity test remains compliant (Table 1), grade 2 is again obtained with the industrial dye-spot test, proving that the pores are still partially unclosed following the hydrothermal treatment alone. Thus, in these conditions the usual hydrothermal sealing fails to occur, meaning there is no fast hydration of the pore walls of the bare anodic film. These results confirm the difficulty, for an anodic film prepared in phosphoric acid electrolyte, of sealing under the usual hydrothermal conditions [27]. This behavior can be explained by the incorporation of phosphate ions into the anodic film during its formation, largely inhibiting the latter’s hydration [22]. The phosphate ions are indeed incorporated into the film in the form of aluminum phosphate AlPO₄ [28,29], which is thermo-dynamically stable. Davis et al. [22] showed that the AlPO₄ top-layer slowly dissolves and that this dissolution is the rate-limiting step inducing greater hydration resistance and thus impeding rapid sealing of the anodic film pores. In all events, our results clearly show that the electrophoretic deposition of boehmite particles allows the complete sealing of the tortuous anodic film prepared in phosphoric acid electrolyte on AA 2024-T3 to be achieved. In this case, the electrophoretic process followed by a hydrothermal post-treatment could jointly accelerate aluminum phosphate dissolution, thus allowing the hydration of the pore walls from alumina (Al₂O₃) to boehmite (AlOOH) (at T > 80°C) and subsequent interaction with the electrodeposited boehmite particles.
Corrosion behavior of the sealed film

Sealed film shows a similar behavior (Figure 2) compared with the bare anodized substrate for the first 50 h of immersion, with the low frequency resistance initially being high (about 5x10^4 Ω·cm²). The R_LF of the sealed film then decreases but remains higher (about 8x10^3 Ω·cm²) compared with the value obtained with the bare anodic film. After 50 h and up to 240 h (i.e. 10 days), the low frequency resistance of the sealed film slowly increases, significantly remaining higher than the value corresponding to the bare anodic film. Thus, this two-step sealing process clearly provides a barrier slowing down the penetration of corrosive species across the anodic film, and significantly improving the anti-corrosion behavior of AA 2024-T3.

Anodized samples with and without electrophoretic impregnation, but each time followed by the same hydrothermal post-treatment, were then characterized using the salt spray test. Figure 6 shows photographs of samples after a salt spray exposure for 24 h. Anodized samples without impregnation and with hydrothermal post-treatment are completely corroded (Figure 6a), whereas anodized samples with impregnation and identical post-treatment show only a few pits (Figure 6b). These results clearly indicate that this two-step sealing process, including electrophoretic deposit before hydrothermal post-treatment, successfully improves corrosion resistance of anodized AA 2024-T3. However, corrosion performances still fail to meet industrial requirements from the duration point of view; although the process can advantageously replace currently used techniques, it still needs to be optimized.
CONCLUSIONS

Anodizing of AA 2024-T3 was performed in phosphoric acid solution, with the resulting bare anodic film showing a low thickness (1.2 ± 0.3 µm) and tortuous porosity. Despite these conditions, the bare anodic film, and especially its barrier layer, provides a first level of protection against corrosion. To boost this protection, a constant cathodic electrophoretic deposition of boehmite particles (\( \Omega_{\text{particles}} = 35\pm15 \text{ nm} \)) dispersed in an aqueous media was conducted, with the resulting deposit being mainly located on the surface. The process was completed by a second step, i.e. an additional hydrothermal post-treatment allowing the anodic film to be completely sealed. Finally, low frequency resistance characterization and three additional tests highlight positive and promising performances against corrosion thanks to the two-step sealing process. The results still fail to meet industrial expectations but the future use of pulsed electrophoresis could possibly offer a promising optimization technique to improve incorporation of the boehmite particles within the tortuous anodic film and thus enhance its anti-corrosion protective behavior.
